AT SOME TIME IN THEIR LIVES, 20% OF MEN AND 10% OF WOMEN IN MOST Western societies will have an alcohol-use disorder, which is defined as repetitive alcohol-related problems in at least 2 of 11 areas of life.1,2 These conditions can decrease the life span by a decade and are associated with severe impairments in social functioning, as well as high rates of medical problems. Although alcohol-related conditions occur in persons from all social strata and affect more than 20% of patients in most medical settings,2,3 few physicians have been adequately trained in identifying and treating these serious problems.

About 50% of persons with alcohol-use disorders have symptoms of alcohol withdrawal when they reduce or discontinue their alcohol consumption; in 3 to 5% of these persons, grand mal convulsions, severe confusion (a delirium), or both develop.1 It is essential that clinicians know how to prevent, recognize, and treat these severe withdrawal states to minimize costly hospitalizations and avoidable deaths.

dromes that require close monitoring to avoid seizures and alcohol withdrawal delirium (delirium tremens).

**WITHDRAWAL DELIRIUM (DELIRIUM TREMENS)**
The criteria for withdrawal delirium, described in Table 2, are delirium (a rapid-onset fluctuating disturbance of attention and cognition, sometimes with hallucinations) plus alcohol withdrawal. Clinicians differ in how well they adhere to these criteria, so it is difficult to determine the prevalence of withdrawal delirium, and rates depend on whether persons with this condition were treated as outpatients, as general medical or psychiatric inpatients, or as patients in an intensive care unit (ICU). Most studies estimate that 3 to 5% of patients who are hospitalized for alcohol withdrawal meet the criteria for withdrawal delirium. Retrospective chart reviews based on diagnoses made by general clinicians show higher but less reliable rates.

Withdrawal delirium usually begins about 3 days after the appearance of symptoms of alcohol withdrawal and lasts from 1 to 8 days or more (usually 2 or 3 days). Approximately 1 to 4% of hospitalized patients who have withdrawal delirium die; this rate could be reduced if an appropriate and timely diagnosis were made and symptoms were adequately treated. Death usually results from hyperthermia, cardiac arrhythmias, complications of withdrawal seizures, or concomitant medical disorders. Delirium during alcohol withdrawal is predicted by the following: CIWA-Ar scores above 15 (especially in association with a systolic blood pressure >150 mm Hg or a pulse rate >100 beats per minute), recent withdrawal seizures (seen in 20% of persons with delirium), prior withdrawal delirium or seizures, older age, recent misuse of other depressant agents, and concomitant medical problems. The latter include electrolyte abnormalities (e.g., low levels of potassium, magnesium, or both), low platelet counts, and respiratory, cardiac, or gastrointestinal disease.

The best approach to the prevention of withdrawal delirium is the identification and treatment of...
preexisting concomitant medical problems and withdrawal syndromes.4 Perhaps because of the low prevalence of withdrawal delirium and the high treatment costs, and because pharmaceutical companies lack profit motives associated with research into new treatments for this condition, few double-blind, controlled, prospective trials of treatments exist. The best evidence is provided in a 2004 review of nine prospective, controlled trials that were conducted between 1959 and 19789 and in subsequent noncontrolled studies that were identified in a PubMed search.

The major treatment goals for withdrawal delirium are to control agitation, decrease the risk of seizures, and decrease the risk of injury and death with the use of the methods outlined in Table 3.7,9,13,18-23 Because of the high prevalence of agitation among patients with withdrawal delirium and the potential lethal outcomes, treatment is best carried out in a locked inpatient ward or an ICU.

The approach to the management of withdrawal delirium includes a careful physical examination and appropriate blood tests to identify and treat medical problems that may have contributed to the severe withdrawal state.9,17 The same general types of support needed for any patient with delirium should be used for the patient with withdrawal delirium, including helping to reorient the patient to time, date, and place, evaluating and treating the patient in a well-lit room, providing reassurance, performing frequent monitoring of vital signs, and ensuring adequate hydration. A functioning intravenous line should be established; care should be taken when administering glucose to avoid precipitating Wernicke’s encephalopathy or thiamine-related cardiomyopathies and to circumvent overhydration in patients who have temporary, alcohol-related, compromised cardiac functioning.18,23 Although thiamine (e.g., 500 mg infused intravenously over the course of 30 minutes once or twice daily for 3 days) and multivitamins are recommended, there is little support for routine administration of magnesium.9,19,20,24 In patients in whom Wernicke’s encephalopathy is suspected, recommended doses of thiamine are even higher (e.g., 500 mg intravenously three times daily for 5 days), in addition to daily parenteral multivitamins.24

The mainstay of the pharmacologic treatment of withdrawal delirium is depressants such as benzodiazepines.7,9,12 No single drug of this class has been shown to be superior to another. Table 3 provides examples of regimens of a drug with a long half-life (diazepam) and of a shorter-acting drug (lorazepam).9,13,18,21 The doses needed to control agitation and insomnia vary dramatically among patients and can be prodigious (e.g., >2000 mg of diazepam in the first 2 days in some patients); this underscores the advisability of providing treatment in a hospital, preferably in an ICU. The severity of symptoms requires that care be directed by clinicians who are well trained in the treatment of this disorder.

Alternative depressant-like drugs have been proposed for uncomplicated withdrawal, but data are lacking regarding their use in persons who have withdrawal delirium. These agents include phenobarbital (up to 1500 mg to 2000 mg administered orally or intravenously on day 1 in patients with delirium13); clomethiazole (not available intravenously, but for uncomplicated withdrawal, up to 2304 mg (12 capsules) can be administered orally in divided doses on day 11,25); midazolam (one study indicated a dose of up to 2800 mg over 50 days); carbamazepine (approximately 800 mg

*The criteria are based on the Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5).1 A patient who meets the criteria for both alcohol withdrawal and delirium is considered to have withdrawal delirium.*
per day); and oxcarbazepine (approximately 900 mg per day).7,26-28

In patients who do not have a response to high doses of benzodiazepines (especially patients who are intubated), propofol may be administered (e.g., 0.3 to 1.25 mg per kilogram of body weight, up to 4 mg per kilogram per hour, for up to 48 hours).20,26 Another adjunctive medication is dexmedetomidine, an α₂-adrenergic agonist that is used in ICUs to produce a state in which the patient is sedated but arousable, with decreased sympathetic tone. Doses up to 0.7 μg per kilogram per hour have been administered in patients who do not have a good response to benzodiazepines.29,30 This drug cannot be used in patients with a heart block, and the patient's blood pressure and heart rate must be closely monitored. None of these regimens have been as well studied as the benzodiazepine regimen, and each has additional dangers and few advantages over benzodiazepines for most patients.21,31-33

Table 3 also lists the potential adjunctive use of haloperidol for severe agitation or hallucinations (0.5–5.0 mg intravenously or intramuscularly every 30–60 min as needed for severe agitation or hallucinosis — not to exceed 20 mg; or 0.5–5.0 mg orally every 4 hr up to 30 mg).

### Table 3. Suggested Treatment of Alcohol Withdrawal Delirium (Delirium Tremens).

| Regimen 1 | 10–20 mg intravenously or orally every 1–4 hr, as needed.
| Regimen 2 | Begin treatment with 5 mg intravenously (2.5 mg/min).9 If needed, repeat 10 min later. If needed, administer 10 mg intravenously 10 min later. If needed, administer 10 mg again 10 min later. If needed, administer 20 mg 10 min later. Continue to administer 5–20 mg/hr, as needed.
| Regimen 1 | Administer 8 mg intravenously, intramuscularly, or orally every 15 min, as needed. After the patient has received 16 mg, if delirium is still severe, administer an 8-mg bolus intravenously. Then administer 10–30 mg/hr.
| Regimen 2 | Administer 1 to 4 mg intravenously every 5–15 min,9 as needed. Alternatively, administer 1–40 mg intramuscularly every 30–60 min, as needed. Continue dosing every hr as needed to maintain somnolence.

In addition to benzodiazepines, administer adjunctive medications such as the antipsychotic agent haloperidol9,21,22 for uncontrolled agitation or hallucinations (0.5–5.0 mg intravenously or intramuscularly every 30–60 min as needed for severe agitation or hallucinosis — not to exceed 20 mg; or 0.5–5.0 mg orally every 4 hr up to 30 mg).

### Conclusions

Withdrawal delirium is an uncommon, serious complication of alcohol withdrawal that is best treated with intravenous benzodiazepines. All the doses described in this review are approximations based on uncontrolled studies. Data on the most effective care for patients with withdrawal delirium are lacking. Since the low potential of profit from this research may undercut interest...
from pharmaceutical companies, treatment trials sponsored by the National Institutes of Health are warranted.
