A 45-year-old nonlactating female presented to the emergency department (ED) fast-track area with a chief complaint of breast pain associated with redness. The symptoms occurred over a period of weeks. There were no constitutional symptoms of fever, chills, or weight loss. The patient had no known personal or family history of breast cancer. On physical examination, there was a 6- by 3-cm confluent area of erythema involving both lower quadrants of the breasts without dimpling. There were no palpable masses, areas of fluctuance, or discharge expressed from the areola. However, it was notable that the patient had large nonaugmented breasts that were difficult to examine. These findings were thought to be most consistent with infectious mastitis, and the patient was started on antibiotics for observation in the ED.

On reexamination of the patient, given the difficulty of direct manual evaluation, ultrasound of the breast was performed with a high-frequency linear array ultrasound probe. A 4- by 4-cm complex structure with both solid and cystic components was visualized 1 cm below the area of erythema (see Movie Clip, online only). The patient was then admitted for evaluation of possible breast cancer versus deep tissue abscess. Initial fine-needle aspiration biopsy revealed diffuse lymphocytic invasion that was nonspecific. However, a later ultrasound-guided core-needle biopsy revealed infiltrating ductal carcinoma.

Distinguishing between breast pathologies, such as simple infectious mastitis, breast abscess, or a malignant condition, can be quite challenging in the ED. A recent study of 127 adult mastitis complaints revealed that only 25% actually represented true simple infectious mastitis. Another 40% were found to be an abscess, and 6% represented a malignant condition. Mammography, while more specific, is often difficult to obtain from the ED. Furthermore, the National Comprehensive Cancer Network endorses ultrasound alongside mammography as a class IIA screening modality for breast cancer with breast skin changes in their 2010 guidelines. This case demonstrates that the potential use of bedside ultrasound by emergency physicians can be a rapid and helpful diagnostic tool in differentiating an uncomplicated infectious condition, mastitis, from more complex pathology, such as breast cancer, that was ultimately diagnosed in this patient.
