We construct metastable configurations of branes and anti-branes wrapping 2-spheres inside local Calabi-Yau manifolds and study their large \(N\) duals. These duals are Calabi-Yau manifolds in which the wrapped 2-spheres have been replaced by 3-spheres with flux through them, and supersymmetry is spontaneously broken. The geometry of the non-supersymmetric vacuum is exactly calculable to all orders of the 't Hooft parameter, and to the leading order in \(1/N\). The computation utilizes the same matrix model techniques that were used in the supersymmetric context. This provides a novel mechanism for breaking supersymmetry in the context of flux compactifications.
1. Introduction

One of the central questions currently facing string theory is how to break supersymmetry in a controllable way. The most obvious ways to break it typically lead to instabilities signaled by the appearance of tachyons in the theory. One would like to find vacua in which supersymmetry is broken, but stability is not lost. It seems difficult (or impossible, at present) to obtain exactly stable non-supersymmetric vacua from string theory. Therefore, the only candidates would appear to be meta-stable non-supersymmetric vacua. This idea has already been realized in certain models (See [1] for a review and the relevant literature). More recently, the fact that metastable vacua are also generic in ordinary supersymmetric gauge theories [2] has added further motivation for taking this method of breaking supersymmetry seriously within string theory. Potential realizations of such metastable gauge theories have been considered in string theory [3] (see also [4]).

The aim of this paper is to study an alternative approach to breaking supersymmetry via metastable configurations, as suggested in [5]. In this scenario, we wrap branes and anti-branes on cycles of local Calabi-Yau manifolds, and metastability is a consequence of the Calabi-Yau geometry. In a sense, this is a geometrically induced metastability. The branes and the anti-branes are wrapped over 2-cycles which are rigid and separated. In order for the branes to annihilate, they have to move, which costs energy as the relevant minimal 2-spheres are rigid. This leads to a potential barrier due to the stretching of the brane and results in a configuration which is metastable. It is particularly interesting to study the same system at large $N$, where we have a large number of branes and anti-branes. In this case, it is better to use a dual description obtained via a geometric transition in which the 2-spheres are shrunk, and get replaced by 3-spheres with fluxes through them. The dual theory has $\mathcal{N} = 2$ supersymmetry, which the flux breaks spontaneously. If we have only branes in the original description, then the supersymmetry is broken to an $\mathcal{N} = 1$ subgroup. With only anti-branes present, we expect it to be broken to a different $\mathcal{N} = 1$ subgroup, and with both branes and anti-branes, the supersymmetry should be completely broken. The vacuum structure can be analyzed from a potential which can be computed exactly using topological string theory [6] or matrix models [7].

Unlike the cases studied before – involving only branes – with branes and anti-branes present, we expect to find a meta-stable vacuum which breaks supersymmetry. We will find that this is the case, and moreover this leads to a controllable way of breaking supersymmetry at large $N$ where to all orders in the ‘t Hooft coupling, but to leading order
in the $1/N$ expansion, we can compute the geometry of the vacua and the low energy Lagrangian.

The organization of this paper is as follows: In section 2 we review the case where we have a single stack of branes and extend it to the case where we have a single stack of anti-branes. In section 3 we discuss the case with more than one $S^2$ in the geometry, and then specialize to the case in which there are only two. We’ll explain how if we have only branes or only anti-branes, supersymmetry is not broken, whereas if we have branes wrapped on one $S^2$ and anti-branes on the other, supersymmetry is spontaneously broken. In section 4 we estimate the decay rate of the metastable vacuum. In section 5 we conclude with open questions and suggestions for future work.

2. Branes and anti-branes on the conifold

Let us begin by recalling the physics of $N$ D5 branes on the conifold singularity. We consider type IIB string theory with the branes wrapping the $S^2$ obtained by resolving the conifold singularity. The local geometry of the Calabi-Yau threefold is a $\mathbb{P}^1$ with normal bundle given by the sum of two line bundles

$$O(-1) + O(-1) \to \mathbb{P}^1$$

At low energies, the field theory on the space-filling D5 branes is a pure $U(N)$ gauge theory with $\mathcal{N} = 1$ supersymmetry. That the theory has $\mathcal{N} = 1$ supersymmetry follows from the fact that string theory on the background of local Calabi-Yau manifolds preserves $\mathcal{N} = 2$, and the D-branes break half of it. In particular, there are no massless adjoint fields, which follows from the important geometric fact that the $\mathbb{P}^1$ which the D5 brane wraps is isolated (its normal bundle is $O(-1) + O(-1)$, which does not have a holomorphic section). In other words, any deformation of the $\mathbb{P}^1$ in the normal direction increases its volume, and so corresponds to a massive adjoint field, at best. (see Fig. 1)
The $\mathcal{N} = 1$ pure Yang-Mills theory on the brane is expected to be strongly coupled in the IR, leading to gaugino bilinear condensation, confinement, and a mass gap. There are $N$ massive vacua corresponding to the gaugino superfield getting an expectation value:

$$
\langle S \rangle = \Lambda_0^3 \exp\left(-\frac{2\pi i\alpha}{N}\right) \exp\left(\frac{2\pi ik}{N}\right) \quad k = 1, \ldots, N
$$

In the future we will suppress the phase factor which distinguishes the $N$ vacua. Above, $\alpha$ is the bare gauge coupling constant defined at the cutoff scale $\Lambda_0$

$$
\alpha(\Lambda_0) = -\frac{\theta}{2\pi} - i \frac{4\pi}{g_{YM}^2(\Lambda_0)},
$$

and $S = \frac{1}{32\pi^2} \text{Tr} W_\alpha W^\alpha$. Recalling that the gauge coupling in this theory runs as

$$
2\pi i\alpha(\Lambda_0) = -\log\left(\frac{\Lambda}{\Lambda_0}\right)^3 N
$$

where $\Lambda$ is the strong coupling scale of the theory, we can also write (2.1) as

$$
\langle S \rangle = \Lambda^3
$$

The theory has an anomalous axial $U(1)_R$ symmetry which rotates the gauginos according to $\lambda \rightarrow \lambda e^{i\phi}$, so

$$
S \rightarrow S e^{2i\phi}.
$$

The anomaly means that this is a symmetry of the theory only provided the theta angle shifts

$$
\theta \rightarrow \theta + 2N\varphi.
$$
Since the theta angle shifts, the tree level superpotential $W_{\text{tree}} = \alpha S$ is not invariant under the R-symmetry, and in the quantum theory additional terms must be generated to correct for this. Adding the correction terms produces the effective Veneziano-Yankielowicz superpotential $W(S)$,

$$W(S) = \alpha S + \frac{1}{2\pi i} NS \left( \log \left( \frac{S}{\Lambda_0^3} \right) - 1 \right)$$

whose critical points are (2.1).

One can also understand the generation of this superpotential from the viewpoint of the large $N$ holographically dual theory $[3]$. This configuration of branes wrapping a $\mathbb{P}^1$ is dual to a closed string theory on the Calabi-Yau manifold obtained by a geometric transition which replaces the wrapped $\mathbb{P}^1$ with a finite sized $S^3$. In the dual theory, the 5-branes have disappeared, and in their place there are $N$ units of Ramond-Ramond flux

$$\int_A H = N$$

through the 3-cycle $A$ corresponding to the $S^3$. Here

$$H = H^{RR} + \tau H^{NS}$$

where $\tau$ is the type IIB dilaton-axion, $\tau = C_0 + \frac{i}{9\pi}$. There are also fluxes turned on through the dual $B$ cycle

$$\int_B H = -\alpha.$$

These fluxes generate a superpotential $[3][4][5]:$

$$W = \int H \wedge \Omega$$

where $\Omega$ is the holomorphic $(3,0)$ form on the Calabi-Yau manifold. This can be written in terms of the periods

$$S = \oint_A \Omega, \quad \frac{\partial}{\partial S} \mathcal{F}_0 = \int_B \Omega$$

as

$$W(S) = \alpha S + N \frac{\partial}{\partial S} \mathcal{F}_0.$$  

(2.6)

Above, $\mathcal{F}_0$ is the prepotential of the $\mathcal{N} = 2$ $U(1)$ gauge theory which is the low-energy effective theory of type IIB string theory on this geometry before turning on fluxes.
For our case, the $B$-period was computed in

$$\frac{\partial}{\partial S} F_0 = \frac{1}{2 \pi i} S (\log(S/\Lambda_0^3) - 1)$$

and so (2.6) exactly reproduces the effective superpotential (2.5) which we derived from gauge theory arguments. Moreover, the superpotential is an F-term which should not depend on the cutoff $\Lambda_0$, so the flux has to run (this agrees with the interpretation of $\Lambda_0$ as an IR cutoff in the conifold geometry which regulates the non-compact $B$-cycle).

$$2\pi i \alpha(\Lambda_0) = -\log(\frac{\Lambda}{\Lambda_0})^{3N}$$

In the dual gauge theory, this corresponds to the running of the gauge coupling in the low energy theory. This theory and the duality were studied from a different perspective in [11] (see also [12]).

2.1. The anti-brane holography

Now consider replacing the D5 branes with anti-D5 branes wrapping the $\mathbb{P}^1$. It is natural that the physics in the presence of the two types of branes should be identical. In particular, in the open string theory, we again expect gaugino condensation, a mass gap and confinement. We conjecture that $N$ antibranes wrapping the $\mathbb{P}^1$ are also holographically dual to the conifold deformation with flux through the $S^3$. In fact, we have no choice but to require this as it is the result of acting by CPT on both sides of the duality. On the open string side, we replace the branes with anti-branes, and on the closed string dual we have $N$ units of flux through the $S^3$, but $N$ is now negative. In other words, the superpotential is still given by (2.5), but with $N < 0$.

At first sight, this implies that there is a critical point as given by (2.1), but now with $N$ negative. However, this cannot be right, since $S$, which is the size of the $S^3$, would grow without bound as we go to weak coupling $S \sim \exp(\frac{8\pi^2}{|N| g_{YM}^2})$. This is clearly unphysical, and moreover the description of the conifold breaks down when $S$ is larger than the cutoff $\Lambda_0^3$ in the dual closed string geometry.

To see what is going on, recall that on the open string side the background has $\mathcal{N} = 2$ supersymmetry, and adding D5 branes preserves an $\mathcal{N} = 1$ subset of this, while adding anti-branes preserves an orthogonal $\mathcal{N} = 1$ subset. By holography, we should have the same situation on the other side of the duality. Namely, before turning on flux, the background has $\mathcal{N} = 2$ supersymmetry, and turning on flux should break this to $\mathcal{N} = 1$. But now
holography implies that depending on whether we have branes or anti-branes in the dual – so depending on the sign of $N$ – we should have one or the other $\mathcal{N} = 1$ subgroup of the supersymmetry preserved. It is clear that the superpotential (2.5) has been adapted to a superspace in which the manifest $\mathcal{N} = 1$ supersymmetry is the one preserved by branes, and hence is not well adapted for the supersymmetry of the anti-branes. Nevertheless, the theory with negative flux should somehow find a way to capture the supersymmetry, as string holography predicts! We will now show that this is indeed the case.

The vacua of the theory are clearly classified by the critical points of the physical potential $V$ of the theory:

$$\partial_S V = 0,$$

where

$$V = g^{S\bar{S}} |\partial_S W|^2.$$  

Above, $g^{S\bar{S}}$ is the Kahler metric for $S$. In this case, the theory has softly broken $\mathcal{N} = 2$ supersymmetry, and so $g$ is given in terms of the prepotential as in the $\mathcal{N} = 2$ case

$$g^{S\bar{S}} = \text{Im}(\tau),$$

where

$$\tau(S) = \partial^2_S F_0 = \frac{1}{2\pi i} \log(S/\Lambda_0^3).$$

With superpotential $W$ as given in (2.6), the effective potential becomes

$$V = \frac{2i}{(\tau - \bar{\tau})} |\alpha + N\tau|^2$$

It is easy to see that the critical points are at

$$\partial_S V = -\frac{2i}{(\tau - \bar{\tau})^2} \partial^3_S F_0 (\alpha + N\tau) (\alpha + N\bar{\tau}) = 0.$$  

This has two solutions. The first is at

$$\alpha + N\tau = 0 \quad (2.7)$$

which solves $\partial W = 0$, and corresponds to (2.1). It is physical when $N$ is positive. The second critical point is at

$$\alpha + N\bar{\tau} = 0. \quad (2.8)$$
Note that in this vacuum, $\partial W \neq 0$. In terms of $S$, it corresponds to

$$\langle S \rangle = \Lambda_0^3 \exp \left( \frac{2\pi i}{|N|} \alpha(\Lambda_0) \right)$$  (2.9)

and is the physical vacuum when $N$ is negative (i.e. where we have $|N|$ anti-branes).

So how can it be that even though $\partial W \neq 0$, supersymmetry is nevertheless preserved? Toward understanding this, recall that before turning on flux, the closed string theory has $\mathcal{N} = 2$ supersymmetry with one $\mathcal{N} = 2$ $U(1)$ vector multiplet $\mathcal{A}$. Adding D5 branes in the original theory corresponds to turning on positive flux, which forces this to decompose into two $\mathcal{N} = 1$ supermultiplets: a chiral multiplet $\mathcal{S}$ containing $S$ and its superpartner $\psi$, and a vector multiplet $W_\alpha$ containing the $U(1)$ gauge field (coming from the 4-form potential decomposed in terms of the harmonic 3-form on $S^3$ and a 1-form in 4d) and the gaugino $\lambda$:

$$\mathcal{A} = (S, W_\alpha)$$

where

$$S = S + \theta \psi + \ldots$$

$$W_\alpha = \lambda_\alpha + \frac{i}{2} (\sigma^{\mu\nu})_\alpha F_{\mu\nu} + \ldots.$$  

The Lagrangian in $\mathcal{N} = 1$ superspace is given by

$$\mathcal{L} = \mathcal{L}_0 + \mathcal{L}_W$$

where

$$\mathcal{L}_0 = \text{Im} \left( \int d^2 \theta d^2 \bar{\theta} \frac{\partial \mathcal{F}_0}{\partial S_i} \frac{\partial \mathcal{F}_0}{\partial S_i} + \int d^2 \theta \frac{1}{2} \frac{\partial^2 \mathcal{F}_0}{\partial S_i \partial S_j} W^\alpha W_\alpha \right)$$

is the action for an $\mathcal{N} = 2$ supersymmetric theory with prepotential $\mathcal{F}_0$, and the superpotential term is

$$\mathcal{L}_W = \int d^2 \theta \mathcal{W}(S) + c.c.$$  

where the superpotential $\mathcal{W}(S)$ is given by (2.8) and is repeated here for the reader’s convenience

$$\mathcal{W}(S) = \alpha S + N \frac{\partial}{\partial S} \mathcal{F}_0.$$  

The puzzle is now what happens in the anti-D5 brane case. Since the Lagrangian with flux apparently has only $\mathcal{N} = 1$ supersymmetry preserved by the D5 branes for any value of $N$, positive or negative, how is it possible that the anti-brane preserves a different $\mathcal{N} = 1$? One might guess that despite the flux, the Lagrangian $\mathcal{L}$ actually preserves the
full $\mathcal{N} = 2$ supersymmetry. This is too much to hope for. In particular, turning on flux should be holographically dual to adding in the branes, which does break half of the $\mathcal{N} = 2$ supersymmetry of the background. Instead, it turns out that the flux breaks $\mathcal{N} = 2$ supersymmetry in a rather exotic way. Namely, which $\mathcal{N} = 1$ is preserved off-shell turns out to be a choice of a “gauge”: we can write the theory in a way which makes either the brane or the antibrane $\mathcal{N} = 1$ supersymmetry manifest, no matter what $\mathcal{N}$ is. On shell however we have no such freedom, and only one $\mathcal{N} = 1$ supersymmetry can be preserved. Which one this is depends only on whether the flux is positive or negative, and not on the choice of the $\mathcal{N} = 1$ supersymmetry made manifest by the lagrangian.

To see how all this comes about, let us try to make the spontaneously broken $\mathcal{N} = 2$ supersymmetry manifest. The $\mathcal{N} = 2$ vector multiplet $A$ is really a chiral multiplet, satisfying the $\mathcal{N} = 2$ chiral constraint $\bar{D}_{i\alpha} A = 0$.

$$A = S + \theta^i \Psi_i + \theta^i \theta^j X_{ij} + \frac{1}{2} (\epsilon_{ij} \theta^i \sigma^{\mu\nu} \theta^j) F_{\mu\nu} + \ldots$$

(2.10)

Here $i, j = 1, 2$ are the $SU(2)_R$ indices, and $\Psi_i$ is a doublet of fermions:

$$\Psi = \left( \begin{array}{c} \psi^i \\ \lambda \end{array} \right).$$

The auxiliary fields $X_{ij}$ of each $\mathcal{N} = 2$ chiral superfield form an $SU(2)_R$ triplet, satisfying a reality constraint

$$\tilde{X}^{ij} = \epsilon_{il} \epsilon_{jk} X^{lk} \equiv X_{ij}. \quad (2.11)$$

In particular, $X^{11} = X^{22} = X_{22}$, and so on.

The action $\mathcal{L}$ can be written in terms of $\mathcal{N} = 2$ superfields, where turning on fluxes in the geometry corresponds to giving a vacuum expectation value to some of the $\mathcal{N} = 2$ F-terms [5][13][14]. Our presentation here follows closely [14]. Namely, consider the Lagrangian

$$\text{Im} \left( \int d^2 \theta_1 d^2 \theta_2 \ F_0(A) \right) + X_{ij} E^{ij} + X^{ij} E_{ij}. \quad (2.12)$$

---

1 More precisely, $A$ is a reduced $\mathcal{N} = 2$ chiral multiplet, meaning it satisfies an additional constraint: $D^{ij} D_{ij} A \sim \nabla^2 A$, where $D_{ij} = D_{i\alpha} D_j^\alpha$, and $\nabla^2$ is the standard laplacian. The reducing constraint says that $\nabla^2 \epsilon_{il} \epsilon_{jk} X^{lk} = \nabla^2 \tilde{X}^{ij}$. This implies that we can shift $X$ by a constant imaginary part that does not satisfy (2.11).
where \( E^{ij} \) is the triplet of Fayet-Iliopolous terms, with same properties as \( X \) has. Since the \( X_{ij} \) transform by total derivatives, the FI term \( X_{ij} E^{ij} \) preserves the \( N = 2 \) supersymmetry. This will match \( \mathcal{L} \) precisely if we set

\[
E^{11} = \alpha = E^{22}, \quad E^{12} = 0
\]

and moreover, we give \( X_{ij} \) a non-zero imaginary part

\[
X_{ij} \rightarrow X_{ij} + iN_{ij}.
\]  

(2.13)

where

\[
N_{11} = 0, \quad N_{22} = 2N, \quad N_{12} = 0.
\]  

(2.14)

It is easy to see from (2.10) that to decompose \( \mathcal{A} \) in terms of \( N = 1 \) multiplets, we can simply expand it in powers of \( \theta_2 \)

\[
\mathcal{A}(\theta_1, \theta_2) = S(\theta_1) + \theta_2^2 W_\alpha(\theta_1) + \theta_2 \theta_2^2 G(\theta_1)
\]  

(2.15)

where the chiral multiplet \( G \) is given by (see, for example [15])

\[
G(y, \theta_1) = \int d^2 \bar{\theta}_1 S(y - i\theta_1 \sigma \bar{\theta}_1, \bar{\theta}_1) = X_{22} + \ldots.
\]

Then, plugging in the vacuum expectation values above in (2.12) and integrating over \( \theta_2 \), we recover the \( N = 1 \) form of \( \mathcal{L} \). More precisely (this will get a nice interpretation later) we recover it, with the addition of a constant term \( 8\pi N/g_{YM}^2 \). Note that by shifting \( X \) we have turned on a non-zero \( F \) term in the \( \theta^2 \) direction off-shell. This breaks \( N = 2 \) supersymmetry, leaving the Lagrangian with only \( N = 1 \) supersymmetry along \( \theta^1 \) direction.

Consider now the vacua of the theory.\(^3\) Let us denote the full \( F \)-term as

\[
\hat{X}_{ij} = X_{ij} + iN_{ij}.
\]

---

\(^2\) Explicitly,

\[
\theta_2 \theta_2 G(\theta_1) = X_{22} \theta_2 \theta_2 + \frac{1}{2} (\epsilon_{ij} \theta i \sigma_{\mu \nu} \theta j)(\theta^2 \sigma^{\mu \nu} \sigma^{\rho} \partial_\rho \psi) + \frac{1}{3!} (\epsilon_{ij} \theta i \sigma_{\mu \nu} \theta j)^2 \nabla^2 S.
\]

See for example [10]

\(^3\) Explicitly, in this language, the F-term potential becomes

\[
\frac{1}{2i} \tau \hat{X}_{ij} \hat{X}^{ij} - \frac{1}{2i} \tau \hat{X}_{ij} \hat{X}^{ij} + \hat{X}_{ij} E^{ij} + \hat{X}^{ij} E_{ij}.
\]

where indices are always raised and lowered with \( \epsilon \) tensor, e.g. \( \hat{X}^{ij} = \epsilon^{ik} \epsilon^{jl} \hat{X}_{kl} \). Moreover, using reality properties of \( \hat{X} \), it is easy to see that \( \hat{X}^{ij} = \hat{X}_{ij} - i(N_{ij} + N^{ij}) \), and the result follows.
Then it is easy to see that \( X \) gets an expectation value,

\[
\langle \hat{X}_{11} \rangle = \frac{2i}{\tau - \bar{\tau}} (\bar{\alpha} + N\bar{\tau})
\]

and

\[
\langle \hat{X}_{22} \rangle = \frac{2i}{\tau - \bar{\tau}} (\alpha + N\bar{\tau})
\]

Now, recall that the physical vacua depend on whether the flux is positive or negative. In particular, in the brane vacuum, where \( N \) is positive, we have \( \alpha + N\tau = 0 \), so

\[
\langle \hat{X}_{11} \rangle = 0, \quad \langle \hat{X}_{22} \rangle \neq 0.
\]

Now, since the supersymmetry variations of the fermions are

\[
\delta \Psi_i = i \hat{X}_{ij} \epsilon^j + \ldots
\]

It follows immediately that in the brane vacuum

\[
\delta \psi = 0, \quad \delta \lambda \neq 0
\]

and \( \lambda \) is the goldstino. The unbroken supersymmetry pairs up \( S \) and \( \psi \) into a chiral field \( S \) and \( \lambda \) and the gauge field into \( W_\alpha \), as in (2.15).

By contrast, in the anti-brane vacuum, \( \alpha + N\bar{\tau} = 0 \), so

\[
\langle \hat{X}_{11} \rangle \neq 0, \quad \langle \hat{X}_{22} \rangle = 0.
\]

Correspondingly, now \( \psi \) is the goldstino:

\[
\delta \psi \neq 0, \quad \delta \lambda = 0
\]

Now the unbroken supersymmetry corresponds to pairing up \( S \) and \( \lambda \) into a chiral field \( \bar{S} \), and \( \psi \) is the partner of the gauge field in \( \bar{W}_\alpha \). In other words, now, it is natural to write \( \mathcal{A} \) as

\[
\mathcal{A} = (\bar{S}, \bar{W}_\alpha)
\]

or, more explicitly:

\[
\mathcal{A}(\theta_1, \theta_2) = \bar{S}(\theta_2) + \theta_1^\alpha \bar{W}_\alpha(\theta_2) + \theta_1 \theta_1 \bar{G}(\theta_2).
\]
It should now be clear how it comes about that even though the Lagrangian \( \mathcal{L} \) has only \( \mathcal{N} = 1 \) supersymmetry, depending on whether the flux \( N \) is positive or negative, we can have different \( \mathcal{N} = 1 \) subgroups preserved on shell. The supersymmetry of the Lagrangian was broken since the flux shifted \( X \) as in (2.13). More precisely, supersymmetry was broken only because this shift of \( X \) could not be absorbed in the field redefinition of \( X \), consistent with (2.11). Off shell, \( X \) is allowed to fluctuate, but because the shift is by \( iN_{ij} \), which is not of the form (2.11), its fluctuations could not be absorbed completely and supersymmetry really is broken. However the shift of \( X \) by \( N_{ij} \) in (2.14) is indistinguishable from shifting \( X \) by
\[
N_{11} = -2N, \quad N_{22} = 0, \quad N_{12} = 0.
\]
(2.19) since the difference between the two shifts can be absorbed into a redefinition of the fields. This would preserve a different \( \mathcal{N} = 1 \) subgroup of the \( \mathcal{N} = 2 \) supersymmetry, the one that is natural in the anti-brane theory. Correspondingly, in all cases, \( \mathcal{N} = 2 \) supersymmetry is broken to \( \mathcal{N} = 1 \) already at the level of the Lagrangian. However, which \( \mathcal{N} = 1 \) is realized off-shell is a gauge choice.

Next we compute the masses of bosonic and fermionic excitations around the vacua. The relevant terms in the \( \mathcal{N} = 2 \) Lagrangian are:
\[
\int d^4 \theta \frac{1}{2} \partial_0^3 \mathcal{F}_0 (\Psi_i \theta^i) (\Psi_j \theta^j) (\hat{X}_{kl} \theta^k \theta^l)
\]
In the present context, we can simplify this as
\[
\frac{1}{2} \partial_0^3 \mathcal{F}_0 (\Psi_1 \Psi_1) \hat{X}_{22} + \frac{1}{2} \partial_0^3 \mathcal{F}_0 (\Psi_2 \Psi_2) \hat{X}_{11}
\]
This gives fermion masses\(^{4}\)
\[
m_{\lambda} = \frac{2i}{(\tau - \bar{\tau})^2} (\bar{\alpha} + N\bar{\tau}) \partial_0^3 \mathcal{F}_0.
\]
For comparison, the mass of the glueball field \( S \) is\(^{5}\)
\[
m_{\mathcal{S}} = \frac{2}{|\tau - \bar{\tau}|^2} \left( |\alpha + N\tau|^2 + |\alpha + N\bar{\tau}|^2 \right)^{\frac{1}{2}} |\partial_0^3 \mathcal{F}_0|.
\]
\(^{4}\) This is the physical mass, with canonically normalized kinetic terms.
\(^{5}\) It is important to note here that the kinetic terms for \( S \) are fixed for us by the string large \( N \) duality, and \( \mathcal{N} = 2 \) supersymmetry. They differ from the “canonical” kinetic terms of \(^{6}\). We are writing here the physical masses, in the basis where all the fields have canonical kinetic terms.
As a check, note that in the brane vacuum (2.7), $\lambda$ is indeed massless as befits the partner of the gauge field (since the original theory had $\mathcal{N} = 2$ supersymmetry, $\lambda$ here is in fact a goldstino!). Moreover, it is easy to see that the masses of $\psi$ and $S$ agree, as they should,

$$|m_S| = \frac{1}{2\pi} \frac{N^2}{|S||\Im(\alpha)|} = |m_\psi|, \quad m_\lambda = 0.$$  

Now consider the case of anti-branes where, in the holographic dual, we have negative flux. This corresponds to the vacuum (2.8). The gauge field $A$ is still massless and $S$ is massive. From (2.8), it follows that in this vacuum it is $\psi$ which is massless, and $\lambda$ becomes massive. Moreover, the mass of $\lambda$ is the same as for $S$.

$$|m_S| = \frac{1}{2\pi} \frac{N^2}{|S||\Im(\alpha)|} = |m_\lambda|, \quad m_\psi = 0.$$  

This is all beautifully consistent with holography!

To summarize, the anti-brane vacuum preserves different supersymmetry than the brane vacuum, and the same is true in the large $N$ dual. In other words the anti-brane/negative flux has oriented the $\mathcal{N} = 1$ supersymmetry differently, as is expected based on the holographic duality.

Let us now try to see if we can understand the anti-brane gluino condensate (2.9) directly from the gauge theory. Before adding in branes, the background has $\mathcal{N} = 2$ supersymmetry. The corresponding supercharges are two weyl fermions $Q, \tilde{Q}$ that transform as a doublet under the $SU(2)_R$ symmetry of the theory. In either vacuum with the branes, only the $U(1)_R$ subgroup of the $SU(2)_R$ symmetry is preserved. If adding in D-branes preserves $Q$, then anti-D branes will preserve $\tilde{Q}$. Since $Q$ and $\tilde{Q}$ transform oppositely under the $U(1)_R$ symmetry, in going from brane to anti-brane, the chirality of the world-volume fermions flips.

The superpotential $\tilde{W}$ that is an honest $F$ term with respect to the supersymmetry preserved by the anti-brane theory, and which reproduces (2.9), is

$$\tilde{W} = \tilde{\alpha} S + \frac{1}{2\pi i} N S(\log(S/\Lambda^3_0) - 1),$$

where $S$ is the anti-brane gaugino condensate, and $N$ is negative. This reflects the fact that, if we keep the background fixed, then $\theta$ transforms under the $R$ symmetry still as (2.4), but the gauginos transform oppositely from before. The rest is fixed by holography – in other words, $\alpha$ is the good chiral field which has $\theta$ as a component. Since it is $\tilde{W}$ that
is the F-term in this case, it is this, and not $\mathcal{W}$, that should be independent of scale for the anti-brane, and hence $\alpha$ should run as

$$2\pi i\alpha(\Lambda_0) = -\log(\frac{\Lambda}{\Lambda_0})^{-3N}$$

Note that this is consistent with turning on the other F-term vev (2.19), which directly preserves the anti-brane supersymmetry.

Finally, consider the value of the potential in the minimum. At the brane vacuum, supersymmetry is unbroken, and

$$V^{\text{brane}} = 0$$

At the anti-brane vacuum, with negative $N$, we have:

$$V^{\text{anti-brane}} = -16\pi \frac{N}{g_{YM}^2} = 16\pi \frac{|N|}{g_{YM}^2}$$

This treats branes and anti-branes asymmetrically. It is natural then to shift the zero of the potential and have

$$V_* = V + 8\pi \frac{N}{g_{YM}^2}$$

which leads to the minimum value

$$V^{\text{anti-brane}}_* = 8\pi \frac{|N|}{g_{YM}^2} = V^{\text{brane}}_*$$

This is equivalent to the inclusion of the constant term which came from the magnetic FI term in the $\mathcal{N} = 2$ theory. Note that this corresponds to the tension of $|N|$ (anti-)branes which is predicted by holography! We thus find a beautiful confirmation for the stringy anti-brane holography.

3. Geometric metastability with branes and anti-brane

There are many ways to naively break supersymmetry in string theory, but they typically lead to instabilities. The simplest example of such a situation is found in type IIB string compactifications on a Calabi-Yau, where one introduces an equal number of $D3$ branes and anti-branes filling the spacetime, but located at points in the Calabi-Yau. Supersymmetry is clearly broken, since branes and anti-branes preserve orthogonal subsets of supersymmetry. This does not typically lead to metastability, however, as one can move branes to where the anti-branes are located, and such a motion would be induced by an
attractive force. This is then similar to a familiar problem in classical electrostatics, and is plagued by the same difficulty as one has in finding locally stable equilibrium configurations of static electric charges.

One way to avoid such an obstacle, as was suggested in [5], is instead of considering branes and anti-branes occupying points in the Calabi-Yau, to consider wrapping them over minimal cycles inside the Calabi-Yau. Moreover, we choose the minimal cycles to be isolated. In other words we assume there is no continuous deformations of the minimal cycles. We wrap branes over a subset \( C_1 \) of such cycles and we wrap the anti-branes over a distinct subset \( C_2 \). In the case of compact Calabi-Yau, it is necessary that the class \([C_1] + [C_2] = 0\), so that there is no net charge (this condition can be modified if we have orientifold planes). Because the branes and anti-branes cannot move without an increase in energy, these will be a metastable equilibrium configurations (see Fig. 2). This is true as long as the cycles \( C_1 \) and \( C_2 \) are separated by more than a string scale distance, so that the geometric reasoning remains valid (when they are closer there are tachyon modes which cause an instability).

![Fig. 2](image_url)

Before antibranes and branes can annihilate one other, they will have to move and meet somewhere, and thus they will have to increase their volume due to the Calabi-Yau geometry.

Here we will consider non-compact examples of this scenario. This decouples the lower dimensional gravity from the discussion, and moreover, the condition that the net class \([C_1] + [C_2] \) be zero is unnecessary as the flux can go to infinity. In particular, we will consider type IIB strings on a non-compact Calabi-Yau threefold where we can wrap 4d space-time filling D5 and anti-D5 branes over different isolated \( S^2 \)'s in the Calabi-Yau. The local geometry of each \( S^2 \) will be the resolved conifold reviewed in the previous section. The only additional point here is that we have more than one such \( S^2 \) in the
same homology class. Moreover, we will consider the large $N$ limit of such brane/anti-brane systems and find that the holographically dual closed string geometry is the same one as in the supersymmetric case with just branes, except that some of the fluxes will be negative. This leads, on the dual closed string side, to a metastable vacuum with spontaneously broken supersymmetry.

We will first describe general geometries of this kind which support meta-stable configurations with both D5 and anti-D5 branes. The relevant Calabi-Yau geometries turn out to be the same ones studied in [3], which led to a non-perturbative formulation of the dual geometry in terms of matrix models [4]. The new twist is that we now allow not just branes, but both branes and anti-branes to be present. We will describe the holographically dual flux vacua. We then specialize to the case of just two $S^2$’s with branes wrapped over one $S^2$ and anti-branes wrapped over the other, and study it in more detail.

3.1. Local multi-critical geometries

Consider a Calabi-Yau manifold given by

$$uv = y^2 + W'(x)^2$$

(3.1)

where

$$W'(x) = g \prod_{k=1}^{n} (x - a_k).$$

If, for a moment, we set $g = 0$, then this is an $A_1$ ALE singularity at every point in the $x$ plane. One can resolve this by blowing up, and this gives a family of $\mathbb{P}^1$, i.e. holomorphic 2-spheres, parameterized by $x$. Let us denote the size of the blown up $\mathbb{P}^1$ by $r$. In string theory, this is complexified by the $B^{NS}$-field\footnote{On the world volume of the D5 brane $B_{NS}$ gets mixed up with the RR potential, so more precisely by $r/g$, we will mean the complex combination of the kahler modulus with $B^{RR} + \tau B^{NS}$. To not have the dilaton turned on, we will in fact keep only the later, setting the geometric size to zero \footnote{11}.}. Turning $g$ back on lifts most of the singularities, leaving just $n$ isolated $\mathbb{P}^1$’s at $x = a_k$. Of course, the $S^2$ still exists over each point $x$, but it is not represented by a holomorphic $\mathbb{P}^1$. In other words, its area is not minimal in its homology class. We have

$$A(x) = (|r|^2 + |W'|^2)^{1/2}.$$

(3.2)
where \( A(x) \) denotes the area of the minimal \( S^2 \) as a function of \( x \). This can be seen by the fact that the equation for each \( x \) is an ALE space and the above denotes the area of the smallest \( S^2 \) in the ALE geometry for a fixed \( x \). Even though the minimal \( P^1 \)'s are now isolated, i.e. at points where \( W' = 0 \), they are all in the same homology class, the one inherited from the ALE space. Note also that the first term, \( |r|^2 \), does not depend on \( x \).

One can now consider wrapping some number of branes \( N_k, k = 1, \ldots, n \) on each \( P^1 \). The case when all \( N_k \)'s are positive and all the branes are D5 branes was studied in [6]. In that case, the gauge theory on the branes is an \( \mathcal{N} = 1 \) supersymmetric \( U(N) \) gauge theory with an adjoint matter field \( \Phi \) and superpotential given by

\[
\text{Tr} W(\Phi) 
\]

where \( W \) is the same polynomial whose derivative is given by \( W'(x) \) in the defining equation of Calabi-Yau [6] [17]. The eigenvalues of \( \Phi \) are identified with positions of the D5 brane on the \( x \)-plane. Here

\[
N = \sum_k N_k
\]

and the choice of distribution of D5 branes among the critical points \( a_k \) corresponds to the choice of a Higgs branch of this supersymmetric gauge theory where, the gauge group is broken

\[
U(N) \to \prod_{k=1}^n U(N_k)
\]

In the low energy limit we have \( \mathcal{N} = 1 \) Yang-Mills theories \( U(N_k) \) with \( \Phi \) field corresponding to a massive adjoint matter for each. Note that (3.3) is consistent with (3.2) in the large \( r \) limit, because wrapping a brane over \( P^1 \) and considering its energy as a function of \( x \), it is minimized along with the area at points where \( W'(x) = 0 \). Furthermore, it is clear from this that the effective coupling constant \( g_{\text{YM}} \) of the four dimensional gauge theory living on the brane is the area of the minimal \( P^1 \)'s times \( 1/g_s \):

\[
\frac{1}{g_{\text{YM}}^2} = \frac{|r|}{g_s}
\]

\[ As explained in [6], the parameters \( g \) and \( a_i \) which enter (3.1) and \( W \) are not dynamical fields, but enter in specifying the theory. This is possible because the Calabi-Yau is non compact. \]
Fig. 3. The brane theory with a tree level physical potential $g_s V(x) = |r| + \frac{1}{32\pi^2} |dW|^2 \approx A(x)$ is depicted along a real line in the $x$-plane for the case where $W$ has two critical points. The potential reflects the Calabi-Yau geometry, and the leading term represents the brane tension.

Below, we will study what happens when some of the $P^1$'s are wrapped with D5 branes and others with anti-D5 branes. By making the vacua $a_i$ very widely separated, the branes and the anti-branes should interact very weakly. Therefore, we still expect to have an approximate $\mathcal{N} = 1$ supersymmetric gauge theory for each brane, with gaugino condensation and confinement at low energies, just as discussed in the previous section. However, because supersymmetry is broken and there are lower energy vacua available where some of the branes annihilate, the system should be only meta-stable. Note that the fact that the $P^1$'s are isolated but in the same class is what guarantees metastability. For the branes to annihilate the anti-branes, they have to climb the potential depicted in Fig. 3. This should be accurate description of the potential when the branes are far away from each other, where the effect of supersymmetry breaking is small. When the branes and anti-branes are very close together – for example when they are within a string distance – there would be tachyon in the theory and the above potential will not be an accurate description. Nevertheless it is clear that the minimum of a brane and anti-brane system is realized when they annihilate each other. We have thus geometrically engineered a metastable brane configuration which breaks supersymmetry. We will discuss aspects of the open string gauge dynamics of this configuration in section 3.6. As we will discuss in that section, unlike the supersymmetric case, there seems to be no simple field theory with a finite number of degrees of freedom which captures the brane/anti-brane geometry. Of course, one can always discuss it in the context of open string field theory.

We have a control parameter for this metastability, which also controls the amount of supersymmetry breaking, which is related to the separation of the critical points $a_i$. The farther apart they are, the more stable our system is. We will discuss stability and decay
rate issues in section 4. In the next subsection, we study the large $N$ holographic dual for this system.

3.2. The large $N$ dual description

The supersymmetric configuration of branes for this geometry was studied in [6], where a large $N$ holographic dual was proposed. The relevant Calabi-Yau geometry was obtained by a geometric transition of (3.1) whereby the $\mathbb{P}^1$'s are blown down and the $n$ resulting conifold singularities at $x = a_k$ are resolved into $S^3$'s by deformations of the complex structure. It is given by

$$uv = y^2 + W'(x)^2 + f_{n-1}(x), \quad (3.4)$$

where $f_{n-1}(x)$ is a degree $n - 1$ polynomial in $x$. As explained in [3], the geometry is effectively described by a Riemann surface which is a double cover of the $x$ plane, where the two sheets come together along $n$ cuts near $x = a_k$ (where the $\mathbb{P}^1$'s used to be). The $A$ and $B$ cycles of the Calabi-Yau project to 1-cycles on the Riemann surface, as in Fig. 4. The geometry is characterized by the periods of the $(3, 0)$ form $\Omega$,

$$S_k = \int_{A_k} \Omega, \quad \partial S_k F_0 = \int_{B_k} \Omega.$$

![Fig. 4](image)

**Fig. 4.** The multi-critical Calabi-Yau geometry projected to the $x$-plane. The cut structure reflects the branching of $y$ over the $x$ plane for $u = v = 0$.

The complex scalars $S_k$ are the scalar partners of the $n U(1)$ vector multiplets under the $\mathcal{N} = 2$ supersymmetry, and $F_0(S)$ is the corresponding prepotential. As before, while (3.4) depends also on $a_i$ and $g$, the latter are just fixed parameters.

19
If, before the transition, all of the $\mathbb{P}^1$'s were wrapped with a large number of branes, the holographically dual type IIB string theory is given by the (3.4) geometry, where the branes from before the transition are replaced by fluxes

$$\int_{A_k} H = N_k, \quad \int_{B_k} H = -\alpha.$$ 

We want to conjecture that this duality holds whether or not all the $N_k \geq 0$. In fact, the discussion of the previous section shows that if all the $N_k \leq 0$ the duality should continue to hold by CPT conjugation. Our conjecture is that it also holds as when some $N_k$ are positive and some negative. The flux numbers $N_k$ will be positive or negative depending on whether we had D5 branes or anti-D5 branes wrapping the $k$'th $\mathbb{P}^1$ before the transition. The flux through the $B_k$ cycles will correspond to the bare gauge coupling constant on the D-branes wrapping the corresponding $\mathbb{P}^1$, and is the same for all $k$ as the $\mathbb{P}^1$'s are all in the same homology class. Turning on fluxes generates a superpotential [9]

$$\mathcal{W} = \int H \wedge \Omega,$$

$$\mathcal{W}(S) = \sum_k \alpha S_k + N_k \partial S_k \mathcal{F}_0.$$  \hspace{1cm} (3.5)

In [3], in the case when all $N_k$'s are positive, the $\mathcal{N} = 1$ chiral superfield corresponding to $S_k$ is identified with the gaugino condensates of the $SU(N_k)$ subgroup of the $U(N_k)$ gauge group factor, $S_k = \frac{1}{32\pi^2} \text{Tr}_{SU(N_k)} W_\alpha W^\alpha$, before the transition. When we have both branes and anti-branes, as long as they are very far separated, this picture should persist. Namely, the brane theory should still have gaugino condensation and confinement, and $S_k$’s should still correspond to the gaugino condensates, even though we expect the supersymmetry to be completely broken in this metastable vacuum. Moreover, for each $k$, there is a remaining massless $U(1)$ gauge field in the dual geometry. It gets identified with the massless $U(1)$ on the gauge theory side which is left over by the gaugino condensation that confines the $SU(N_k)$ subgroup of the $U(N_k)$ gauge theory.

In the supersymmetric case studied in [3], the coefficients of the polynomial $f(x)$ determining the dual geometry and the sizes of $S_i$ is fixed by the requirement that

$$\partial S_k W(S) = 0$$

20
and this gives a supersymmetric holographic dual. In the case of interest for us, with mixed fluxes, we do not expect to preserve supersymmetry. Instead we should consider the physical potential $V(S)$ and find the dual geometry by extremizing

$$\partial_{S_k} V(S) = 0$$

which we expect to lead to a metastable vacuum. The effective potential $V$ is given in terms of the special geometry data and the flux quanta:

$$V = g^{S_i \bar{S}_j} \partial_{S_i} W \bar{\partial}_{S_j} W$$

where the Kahler metric is given by $g_{ij} = \text{Im}(\tau_{ij})$ in terms of the period matrix of the Calabi-Yau

$$\tau_{ij} = \partial_{S_i} \partial_{S_j} \mathcal{F}_0.$$ 

In terms of $\tau$, we can write

$$V = \left( \frac{2i}{\tau - \bar{\tau}} \right)^{jk} (\alpha_j + \tau_{jj'} N^{j'})(\bar{\alpha}_k + \bar{\tau}_{kk'} N^{k'})$$

where we have all the $\alpha_j = \alpha$. To be explicit, we consider in detail the case where we have only two $S^3$'s in the dual geometry before turning to the more general case.

### 3.3. More precise statement of the conjecture

Let us make our conjecture precise: We conjecture that the large $N$ limit of brane/anti-brane systems are Calabi-Yaus with fluxes. In particular, the solutions to tree level string equations on the closed string side lead to an all order summation of planar diagrams of the dual brane/anti-brane system (i.e. to all orders in the $\text{'}t$ Hooft coupling). We translate this statement to mean that the geometry of the closed string vacuum at tree level is captured by extremizing the physical potential. Moreover the physical potential is characterized by the fluxes (which fix the superpotential) as well as by the Kahler potential; the main ingredient for both of these objects is the special geometry of the Calabi-Yau after transition. This, in turn, is completely fixed by tree level topological string theory, or equivalently by the planar limit of a certain large $N$ matrix model [1]. Here we are using the fact that since $\mathcal{N} = 2$ is softly broken by the flux terms, the special Kahler metric is unaffected at the string tree level. It is quite gratifying to see that topological objects,
such as matrix integrals, play a role in determining the geometry of non-supersymmetric string vacua!

Of course the Kahler potential should be modified at higher string loops since. In particular the $1/N$ corrections to our duality should involve such corrections. Note that, in the supersymmetric case studied in [3], there were no $1/N$ corrections to modify the geometry of the vacua. We do expect the situation to be different in the non-supersymmetric case. Note however, from the discussion of section 2, the soft breaking is such that it is ambiguous which $\mathcal{N} = 1$ supersymmetry the Lagrangian has. This should constrain what kind of quantum corrections one can have beyond those allowed by a generic soft breaking. This deserves further study.

3.4. The case of 2 $S^3$’s

For simplicity we start with the case where we have just two $S^3$’s. Before the transition, there are two shrinking $\mathbb{P}^1$’s at $x = a_{1,2}$. Let us denote by $\Delta$ the distance between them,

$$\Delta = a_1 - a_2.$$  

The theory has different vacua depending on the number of branes we put on each $\mathbb{P}^1$. The vacua with different brane/antibrane distributions are separated by energy barriers. To overcome these, the branes must first become more massive.

The effective superpotential of the dual geometry, coming from the electric and magnetic FI terms turned on by the fluxes, is

$$W(S) = \alpha(S_1 + S_2) + N_1 \partial S_1 \mathcal{F}_0 + N_2 \partial S_2 \mathcal{F}_0$$

The B-periods have been computed explicitly in [3]. We have

$$2\pi i \partial_{S_1} \mathcal{F}_0 = W(\Lambda_0) - W(a_1) + S_1(\log(S_1 \frac{S_1}{g\Delta^3}) - 1) - 2(S_1 + S_2) \log(\frac{\Lambda_0}{\Delta}) + (2S_1^2 - 10S_1S_2 + 5S_2^2)/(g\Delta^3) + \ldots$$

and

$$2\pi i \partial_{S_2} \mathcal{F}_0 = W(\Lambda_0) - W(a_2) + S_2(\log(S_2 \frac{S_2}{g\Delta^3}) - 1) - 2(S_1 + S_2) \log(\frac{\Lambda_0}{\Delta}) - (5S_1^2 - 10S_1S_2 + 2S_2^2)/(g\Delta^3) + \ldots$$
where the omitted terms are of order $S_1^{n_2} S_2^{n_2} / (g \Delta^3)^{n_1 + n_2 - 1}$, for $n_1 + n_2 > 2$. In the above, $\Lambda_0$ is the cutoff used in computing the periods of the non-compact $B$ cycles, and physically corresponds to a high energy cutoff in the theory.

To the leading order (we will justify this aposteriori), we can drop the quadratic terms in the $S_k g \Delta$’s, and higher. To this order,

$$2\pi i \tau_{11} = 2\pi i \partial^2_{S_1} F_0 \approx \log \left( \frac{S_1}{g \Delta^3} \right) - \log \left( \frac{\Lambda_0}{\Delta} \right)^2$$

$$2\pi i \tau_{12} = 2\pi i \partial_{S_1} \partial_{S_2} F_0 \approx - \log \left( \frac{\Lambda_0}{\Delta} \right)^2$$

$$2\pi i \tau_{22} = 2\pi i \partial^2_{S_2} F_0 \approx \log \left( \frac{S_2}{g \Delta^3} \right) - \log \left( \frac{\Lambda_0}{\Delta} \right)^2$$

In particular, note that at the leading order $\tau_{12}$ is independent of the $S_i$, so we can use $\tau_{ii}$ as variables. It follows easily that the minima of the potential are at

$$Re(\alpha) + Re(\tau)_{ij} N^j = 0$$

and

$$Im(\alpha) + Im(\tau)_{ij} |N^j| = 0$$

For example, with branes on the first $\mathbf{P}^1$ and anti-branes on the second, $N_1 > 0 > N_2$,

$$\langle S_1 \rangle = g \Delta^3 \left( \frac{\Lambda_0}{\Delta} \right)^2 \left( \frac{\Lambda_0}{\Delta} \right)^2 |N_2| e^{-2\pi i \alpha_i / |N_1|}$$

$$\langle S_2 \rangle = g \Delta^3 \left( \frac{\Lambda_0}{\Delta} \right)^2 \left( \frac{\Lambda_0}{\Delta} \right)^2 |N_1| e^{2\pi i \alpha_i / |N_2|}.$$  \hfill (3.9)

To see how to interpret this, let us recall the supersymmetric situation when $N_1, N_2 > 0$. There, to the same order, one finds

$$\langle S_1 \rangle = g \Delta^3 \left( \frac{\Lambda_0}{\Delta} \right)^{2(1+|N_2|)} e^{-2\pi i \alpha_i / |N_1|}$$

$$\langle S_2 \rangle = g \Delta^3 \left( \frac{\Lambda_0}{\Delta} \right)^{2(1+|N_1|)} e^{-2\pi i \alpha_i / |N_2|}.$$  \hfill (3.10)

The interpretation of the above structure in the supersymmetric case is as follows. In the IR, the theory flows to a product of two supersymmetric gauge theories with gauge group $U(N_1) \times U(N_2)$, where each $U(N_i)$ factor is characterized by a scale $\Lambda_i$,

$$\langle S_1 \rangle = \Lambda_1^3, \quad \langle S_2 \rangle = \Lambda_2^3.$$  \hfill (3.11)

Let us denote by $\alpha_{1,2}$ the the bare coupling constants of the low energy theory $U(N_1)$ and $U(N_2)$ theories, i.e.

$$2\pi i \alpha_i = - \log \left( \frac{\Lambda_i}{\Lambda_0} \right)^{3|N_i|}, \quad i = 1, 2$$  \hfill (3.12)
On the one hand, we can simply read them off from (3.10) since we can write (3.11) as
\[ \langle S_i \rangle = \Lambda_0^3 e^{-2\pi i \alpha_i / |N_i|} \]

\[
2\pi i \alpha_1 = 2\pi i \alpha + \log(\frac{\Lambda_0}{m_\Phi})^{|N_1|} - 2 \log(\frac{\Lambda_0}{m_W})^{|N_1|} \\
2\pi i \alpha_2 = 2\pi i \alpha + \log(\frac{\Lambda_0}{m_\Phi})^{|N_2|} - 2 \log(\frac{\Lambda_0}{m_W})^{|N_2|}
\tag{3.13}
\]

We could also have obtained this by using the matching relations with the high energy coupling \( \alpha \). Namely, in flowing from high energies we have to take into account the massive fields we are integrating out. The fields being integrated out in this case are the massive adjoint \( \Phi \) near each vacuum, whose mass goes as \( m_\Phi = g \Delta \), and the massive \( W \) bosons in the bifundamental representation, whose masses are \( m_W = \Delta \). The standard contribution of these heavy fields to the running coupling constant is simply what is written in (3.13).

In the non-supersymmetric case, from (3.11) and (3.12), we can write the gaugino vevs in (3.9) very suggestively exactly as in (3.13) except that we replace

\[ \Lambda_0^{[N_1]+[N_2]} \rightarrow \Lambda_0^{[N_1]} \Lambda_0^{[N_2]} \]

and

\[ m_W \rightarrow \overline{m}_W \]

leading to

\[
2\pi i \alpha_1 = 2\pi i \alpha + \log(\frac{\Lambda_0}{m_\Phi})^{[N_1]} - 2 \log(\frac{\Lambda_0}{m_W})^{[N_1]} \\
2\pi i \alpha_2 = 2\pi i \alpha + \log(\frac{\Lambda_0}{m_\Phi})^{[N_2]} - 2 \log(\frac{\Lambda_0}{m_W})^{[N_2]}
\tag{3.14}
\]

which gives back (3.9). In other words, the leading result is as in the supersymmetric case, except that branes of the opposite type lead to complex conjugate running. In particular, this implies that the real part of the coupling runs as before, but the \( \theta \)-angle is running differently due to the matter field coming between open strings stretched between the branes and anti-branes. We will discuss potential explanations of this in section 3.6, where we discuss the matter structure in the brane/anti-brane system.
The potential at the critical point is given by:

\[ V_{s^+} = \frac{8\pi}{g^2_{YM}} (|N_1| + |N_2|) - \frac{2}{\pi} |N_1||N_2| \log \frac{\Lambda_0}{m_W}^2 \]  

(3.15)

The first term, in the holographic dual, corresponds to the tensions of the branes. The second term should correspond to the Coleman-Weinberg one loop potential which is generated by zero point energies of the fields. This interpretation coincides nicely with the fact that this term is proportional to $|N_1||N_2|$, and thus comes entirely from the $1-2$ sector of open strings with one end on the branes and the other on the anti-branes. The fields in the $1-1$ and $2-2$ sectors with both open string endpoints on the same type of brane do not contribute to this, as those sectors are supersymmetric and the boson and fermion contributions cancel. We shall return to this in section 3.6. For comparison, in the case of where both $\mathbb{P}^1$'s were wrapped by D5 branes, the potential at the critical point $V_{s^+}$ equals

\[ V_{s^+} = \frac{8\pi}{g^2_{YM}} (|N_1| + |N_2|) = V_{s^-} \]

and is the same as for all anti-branes. This comes as no surprise, since the tensions are the same, and the interaction terms cancel since the theory is now truly supersymmetric.

We now consider the masses of bosons and fermions in the brane/anti-brane background. With supersymmetry broken, there is no reason to expect the 4 real bosons of the theory, coming from the fluctuations of $S_{1,2}$ around the vacuum, to be pairwise degenerate. To compute them, we simply expand the potential $V$ to quadratic order. More precisely, to compute the physical masses as opposed to the naive hessian of the potential, we have to go to the basis where kinetic terms of the fields are canonical. The computation is straightforward, if somewhat messy. At the end of the day, we get the following expressions.

\[ (m_{\pm}(c))^2 = \frac{(a^2 + b^2 + 2abc) \pm \sqrt{(a^2 + b^2 + 2abc)^2 - 4a^2b^2(1 - v)^2}}{2(1 - v)^2} \]

8 We have shifted the overall zero point energy of $V$ as we did in the previous section, to make the brane and the anti-brane tensions equal. More precisely, we set

\[ V \rightarrow V + \frac{8\pi}{g^2_{YM}} (N_1 + N_2). \]
where $c$ takes values $c = \pm 1$, and

$$a \equiv \left| \frac{N_1}{2\pi \Lambda_3^2 \text{Im} \tau_{11}} \right|, \quad b \equiv \left| \frac{N_2}{2\pi \Lambda_3^2 \text{Im} \tau_{22}} \right|$$

$$v \equiv \frac{(\text{Im} \tau_{12})^2}{\text{Im} \tau_{11} \text{Im} \tau_{22}}.$$ 

Indeed we find that our vacuum is metastable, because all the $m^2 > 0$ (which follows from the above formula and the fact that $v < 1$ in the regime of interest $|S_i/g\Delta^3| < 1$). This is a nice check on our holography conjecture, as the brane/anti-brane construction was clearly metastable. Moreover, we see that there are four real bosons, whose masses are generically non-degenerate, as expected for the spectrum with broken supersymmetry.

Since supersymmetry is completely broken from $\mathcal{N} = 2$ to $\mathcal{N} = 0$, we expect to find 2 massless Weyl fermions, which are the Goldstinos. More precisely, we expect this only at the closed string tree level (i.e. at the leading order in $1/N$ expansion). Namely, at string tree level, we can think about turning on the fluxes as simply giving them an “expectation value”, which would break the $\mathcal{N} = 2$ supersymmetry spontaneously. However, at higher orders, the Kahler potential should a priori not be protected in that breaking is soft, and not spontaneous. This will affect the computation of the mass terms in section 2, which relied on the $\mathcal{N} = 2$ relation between the Kahler potential and the superpotential, and should result in only one massless fermion remaining. Masses of the fermions are computed from the $\mathcal{N} = 2$ Lagrangian, as in section two, but now with two vector multiplets. We again redefine the fields so as to give them canonical kinetic terms. We indeed find two massless fermions, at the order at which we are working at. Since supersymmetry is broken these are interpreted as the Goldstinos (we will give a more general argument in the next subsection). There are also two massive fermions, with masses

$$m_{\Omega_1} = \frac{a}{1 - v}, \quad m_{\Omega_2} = \frac{b}{1 - v},$$

Note that $v$ controls the strength of supersymmetry breaking. In particular when $v \to 0$ the 4 boson masses become pairwise degenerate and agree with the two fermion masses $a$ and $b$, as expected for a pair of $\mathcal{N} = 1$ chiral multiplets.

The mass splitting between bosons and fermions is a measure of the supersymmetry breaking. In order for supersymmetry breaking to be weak, these splittings have to be small. There are two natural ways to make supersymmetry breaking be small: One way is to take the number of anti-branes to be much smaller than the number of branes. The
other way is to make the branes and anti-branes be very far from each other. We will consider mass splittings in both of these cases.

Adding a small anti-brane charge should be a small perturbation to a system of a large number of branes. In that context, the parameter that measures supersymmetry breaking should be $|N_2/N_1|$, where $|N_2|$ is the number of anti-branes. Let us see how this is reflected in $v$. We should see that in this limit, $v$ becomes small.

Note that (3.9) implies that

$$
\frac{|S_1|}{g \Delta^3}^{\frac{|N_2|}{N_1}} = \frac{|S_2|}{g \Delta^3}^{\frac{|N_1|}{N_2}} = \frac{\Lambda}{\Delta}^{2(|N_1|+|N_2|)} = \exp\left(-\left(1-\delta\right)\frac{8\pi^2}{g_{YM}^2}\right)
$$

with

$$
\delta \equiv \left(\frac{g_{YM}^2}{2\pi}\right)^2 (|N_1|+|N_2|) \log \frac{\Lambda_0}{\Delta}.
$$

Note that

$$
\frac{\delta}{1-\delta} = \left|\log \frac{\Lambda_0/\Delta}{\log \Delta/\Lambda}\right|.
$$

(3.16)

For finite non-vanishing $S_i/g \Delta^3$, clearly $\delta$ is very close to 1 because of the fact that $g_{YM}^2$ is very small for large cutoff $\Lambda_0$. Of course, this is compatible with the definition of $\delta$ as we recall the running of $g_{YM}^2$. Therefore, let us write

$$
\delta = 1 - \epsilon
$$

We then have (without any approximation)

$$
v = \frac{(\text{Im} \tau_{12})^2}{\text{Im} \tau_{11} \text{Im} \tau_{22}} = \frac{(1 - \epsilon)^2}{(1 + \epsilon^2) + \epsilon\left(\frac{N_2}{N_1} + \frac{N_1}{N_2}\right)}
$$

(3.17)

And in the limit of $\frac{|N_1|}{|N_2|} \to \infty$ (or similarly when $\frac{|N_2|}{|N_1|} \to \infty$) we find that $v \to 0$. This is as expected, since in this limit we expect supersymmetry breaking to be very small.

Below are plots of the masses for nonsupersymmetric vacua, with fixed $|N_1 N_2|$ but varying $\log \left|\frac{N_2}{N_1}\right|$. They demonstrate how mass splitting vanishes in the extreme limits of the ratio $N_1/N_2$, where supersymmetry is restored.
Fig. 5. Here we depict the masses of the four bosons as solid lines and the two non-vanishing fermionic masses as dashed lines. The other two fermions, not shown here, are massless Goldstinos. Note that supersymmetry breaking is most pronounced when $|N_1| = |N_2|$. This plot is for fixed $|N_1 N_2|$, as we vary $|N_1/N_2|$.

It is also natural to consider the mass splittings in the limit of large separation of branes, where supersymmetry is expected to be restored. We have to be somewhat careful in taking this limit. It turns out that the right limit is when

$$|\Lambda| << |\Delta| << |\Lambda_0|$$

and where

$$|\Delta/\Lambda| >> |\Lambda_0/\Delta|$$

which implies from (3.16) that $\delta \to 0$ and from (3.17) we have $v \to 0$ and thus the mass splittings disappear as expected.

It is also interesting to write the energy of the vacuum (3.15) as a function of $v$. In particular let $\Delta E$ represent the shift in energy from when the branes are infinitely far away from one another. Then we find from (3.15) that

$$\frac{\Delta E}{E} = -\frac{\delta}{\sqrt{|N_1|/|N_2|} + \sqrt{|N_2|/|N_1|)^2}}$$
Note that the energy shift goes to zero as \(|N_2/N_1| \to 0, \infty\) as expected. It also goes to zero in the large brane/anti-brane separation, because then \(\delta \to 0\). The sign of the shift is also correct, as one would expect that the attraction between the branes and the anti-branes should decrease the energy of the system. Note also that for fixed \(|N_1N_2|, \Delta E/E\), as well as the mass splittings, is maximal when \(N_1 = -N_2\), i.e. when we have equal number of branes and anti-branes, whereas if one of them is much larger than the other, mass splittings as well as \(\Delta E/E \to 0\). This is again consistent with the fact that in the limit with an extreme population imbalance of branes, the supersymmetry breaking goes away.

3.5. \(n \ S^3\)’s

Let us now generalize our analysis to the case with an arbitrary number of blown up \(S^3\)’s. In this case, before the geometric transition there are \(n\) shrinking \(\mathbb{P}^1\)’s located at \(x = a_i, i = 1, 2, \ldots, k\). We will denote the distance between them as

\[
\Delta_{ij} = a_i - a_j
\]

As in the simpler case, for a specified total number of branes, we can classify the vacua of the theory by the distribution of the branes among the \(\mathbb{P}^1\)’s, and these vacua will be separated by potential barriers corresponding to the increase in the size of the wrapped \(\mathbb{P}^1\) between critical points.

The effective superpotential of the dual geometry after the geometric transition, in which the branes have been replaced by fluxes, is given by \((3.4)\). The B-periods will now take the form

\[
2\pi i \partial S_i \mathcal{F}_0 = S_i \log \frac{S_i}{W^n(a_i)\Lambda_0^n} + \sum_{j \neq i} S_j \log \left( \frac{\Delta_{ij}^2}{\Lambda_0^n} \right) + \ldots
\]

where again, \(\Lambda_0\) is interpreted as a UV cutoff for the theory, and we are omitting terms analogous to the polynomial terms in the example of the last section.

To leading order, the generalization of the 2 \(S^3\) case to the current situation is straightforward. We have

\[
2\pi i \tau_{ii} = 2\pi i \partial^2 S_i \mathcal{F}_0 \approx \log \left( \frac{S_i}{W^n(a_i)\Lambda_0^n} \right)
\]

\[
2\pi i \tau_{ij} = 2\pi i \partial S_i \partial S_j \mathcal{F}_0 \approx - \log \left( \frac{\Lambda_0^n}{\Delta_{ij}^2} \right)
\]
The potential (3.7) has its critical points where

$$\partial S_i V = \frac{i}{2} F_{ijl} g^{S_j S_l} (\bar{\alpha_j} + \bar{\tau}_{jj} N_j)(\alpha_k + \bar{\tau}_{kk} N_k^*) = 0$$  \hspace{1cm} (3.18)$$

The solutions which correspond to minima are then determined by

$$\text{Re}(\alpha) + \text{Re}(\tau)_{ij} N_j^i = 0$$

and

$$\text{Im}(\alpha) + \text{Im}(\tau)_{ij} |N_j^i| = 0$$

Indeed, in the case where all $N^i$ are either positive (negative), these are just the (non-)standard F-flatness conditions of the $\mathcal{N} = 1$ supersymmetric theory, so they will be satisfied exactly. In the non-supersymmetric cases, the conditions will receive perturbative corrections coming from the corrections to the Kahler potential at higher string loops.

The expectation values of the bosons $S^i$ take a natural form in these vacua, being given by

$$\langle S_i \rangle = W''(a_i) \Lambda_0^2 \prod_{j \neq i}^{N_i > 0} \left( \frac{\Lambda_0}{\Delta_{ij}} \right)^{2|N_i|} \prod_{k \neq i}^{N_k < 0} \left( \frac{\Lambda_0}{\Delta_{ik}} \right)^{2|N_i|} \exp \left( -\frac{2\pi i \alpha}{|N_i^i|} \right), \quad N_i > 0$$

$$\langle S_i \rangle = W''(a_i) \Lambda_0^2 \prod_{j \neq i}^{N_i > 0} \left( \frac{\Lambda_0}{\Delta_{ij}} \right)^{2|N_i|} \prod_{k \neq i}^{N_k < 0} \left( \frac{\Lambda_0}{\Delta_{ik}} \right)^{2|N_i|} \exp \left( \frac{2\pi i \alpha}{|N_i^i|} \right), \quad N_i < 0$$

The explanation of these expectation values is the natural generalization of the case from the previous section. We characterize each gauge theory in the IR by a scale $\Lambda_i$, where $S_i = \Lambda_i^3$. The massive adjoints near the $i$’th critical point now have $m_{\Phi_i} = W''(a_i)$, whereas the massive $W$ bosons have mass $m_W = \Delta_{ij}$. Then matching scales, we find

$$\langle S_i^{\text{brane}} |N_i^i| = \Lambda_i^3 |N_i^i| = e^{-2\pi i \alpha} \Lambda_0^{2N_{\text{brane}}} \Lambda_0^{2N_{\text{antibrane}}} m_{\Phi_i}^{N_i^i} \prod_{j \neq i}^{\text{same}} m_W N_j \prod_{j \neq i}^{\text{opposite}} \frac{1}{m_W}$$

$$\langle S_i^{\text{antibrane}} |N_i^i| = \Lambda_i^3 |N_i^i| = e^{2\pi i \alpha} \Lambda_0^{2N_{\text{brane}}} \Lambda_0^{2N_{\text{antibrane}}} m_{\Phi_i}^{N_i^i} \prod_{j \neq i}^{\text{same}} m_W N_i \prod_{j \neq i}^{\text{opposite}} \frac{1}{m_W}$$

Above, $N_{\text{brane}}$ and $N_{\text{anti-brane}}$ are the total number of branes and anti-branes, respectively, and the products are over the sets of branes of the same and opposite types as the brane in question. In the supersymmetric case, this reduces to the expected relation between the
scales. The non-supersymmetric case is, to leading order, identical except that the branes of opposite type contribute complex conjugate running, which is explained in section 3.6.

Similarly to the $2S^3$ case, the gauge coupling constant in each $U(N_k)$ factor will run as

$$2\pi\alpha_i = 2\pi\alpha + \log\left(\frac{\Lambda_0}{m_{\Phi_i}}\right) + \sum_{j \neq i}^{\text{same}} \log\left(\frac{\Lambda_0}{m_{W_{ij}}}\right) - 2 \sum_{j \neq i}^{\text{opposite}} \log\left(\frac{\Lambda_0}{m_{W_{ij}}}\right),$$

for a brane, ($N_i > 0$). For antibrane, ($N_i < 0$) and the running is

$$2\pi\alpha_i = 2\pi\alpha + \log\left(\frac{\Lambda_0}{m_{\Phi_i}}\right) + \sum_{j \neq i}^{\text{same}} \log\left(\frac{\Lambda_0}{m_{W_{ij}}}\right) - 2 \sum_{j \neq i}^{\text{opposite}} \log\left(\frac{\Lambda_0}{m_{W_{ij}}}\right).$$

This again has a simple form corresponding to integrating out massive adjoints and $W$ bosons. Moreover, the fields corresponding to strings with both endpoints on branes, or on the anti-branes, contribute to running of the gauge coupling as in the supersymmetric case. The fields coming from strings with one end on the brane and the other on the anti-brane, again give remarkably simple contributions, almost as in the supersymmetric case: the only apparent difference being in how they couple to the $\theta$ angle. We will come back to this later.

One could in principle compute the masses of the bosons and fermions in a generic one of these vacua. We will not repeat this here. Instead, let us just try to understand the massless fermions, or the structure of supersymmetry breaking in this theory. The results of section 2 are easy to generalize, to find the fermion mass matrices

$$m_{\psi_i\psi_j} = -\frac{i}{2} g S_i S_k F_{ijl}(\alpha_k + \bar{\tau}_{kk'} N^{k'})$$

$$m_{\lambda_i\lambda_j} = -\frac{i}{2} g S_i S_k F_{ijl}(\bar{\alpha}_k + \bar{\tau}_{kk'} N^{k'}).$$

In the above, the repeated indices are summed over, and we have denoted

$$F_{ijk} = \frac{\partial^3 F_0}{\partial S_i \partial S_j \partial S_k}.$$
At the order to which we are working (corresponding to one loop on the field theory side), $\mathcal{F}_{ijk}$ is diagonal. The masses then imply that in vacua where the standard F-term
\[
\partial_S W = \alpha_i + \tau_{ij} N^j
\]
fails to vanish, a zero eigenvalue is generated for the $\psi$ mass matrix, while when the non-standard F-term
\[
\partial_{\bar{S}} \bar{W} = \bar{\alpha}_i + \bar{\tau}_{ij} N^j
\]
fails to vanish, a zero eigenvalue is generated for the $\lambda$ mass matrix.

More generally, note that the exact conditions (at leading order in $1/N$) for critical points of the potential (3.18) can be re-written in terms of the fermion mass matrices as
\[
m_{\psi_i \psi_j} g^{S_j S_k} (\bar{\alpha}_k + \bar{\tau}_{kk'} N^{k'}) = 0 \quad (3.19)
\]
\[
m_{\lambda_i \lambda_j} g^{S_j S_k} (\alpha_k + \tau_{kk'} N^{k'}) = 0. \quad (3.20)
\]
In the case when supersymmetry is unbroken, and all the $\mathbb{P}^1$'s are wrapped by branes, we will find both of these equations to be truly exact, and satisfied trivially: the $\lambda$ mass matrix vanish identically, so (3.20) is trivial, and (3.19) is satisfied without constraining $m_{\psi_i \psi_j}$ directly since the vanishing of $(\alpha_k + \tau_{kk'} N^{k'})$ is the F-flatness condition. A similar story holds in the anti-brane vacuum.

In the case with both branes and antibranes, the equations are not trivial. Instead, they say that both the $\psi$- and the $\lambda$-mass matrices have at least one zero eigenvalue. At the string tree level (i.e at the leading order in $1/N$ expansion), we expect them to have exactly one zero eigenvalue each. To this order, we can think about turning on the fluxes as simply giving them an “expectation value”, which would break the $\mathcal{N} = 2$ supersymmetry spontaneously. However, at higher orders, the Kahler potential is not protected in that the symmetry breaking is soft, but not spontaneous. Consequently, the form of the equations (3.19),(3.20) should presumably receive corrections, and only one massles fermion should remain, corresponding to breaking $\mathcal{N} = 1$ to $\mathcal{N} = 0$.

The leading-order potential in these vacua is given by

\[
V_* = \frac{8\pi}{g_{YM}^2} \left( \sum_i |N_i| \right) - \left( \sum_{i,j}^{N_i>0, N_j<0} \frac{2}{\pi} |N_i| |N_j| \log \left| \frac{\Lambda_0}{\Delta_{ij}} \right| \right)
\]
This takes the natural form of a brane-tension contribution for each brane in the system, plus interaction terms between the brane/anti-brane pairs. If we define

$$\delta_{ij} \equiv \left( \frac{g_{\text{YM}}}{2\pi} \right)^2 \left( \sum_k |N_k| \right) \log \left| \frac{\Lambda_0}{\Delta_{ij}} \right|.$$ 

Then in terms of these parameters $\delta_{ij}$, the physical potential takes the simpler form of

$$V_* = \frac{8\pi}{g_{\text{YM}}^2} \left( \sum_i |N_i| - \frac{\sum_{i,j}^{N_i>0,N_j<0} \delta_{ij} |N_i||N_j|}{\sum_i |N_i|} \right)$$

so that the energy shift is

$$\frac{\Delta E}{E} = -\frac{\sum_{i,j}^{N_i>0,N_j<0} \delta_{ij} |N_i||N_j|}{(\sum_i |N_i|)^2}.$$ 

Once again, the forces among the (anti-)branes cancel. Moreover, the branes and the anti-branes attract, which lowers the energy of the vacuum, below the supersymmetric one. This energy shift will effectively vanish only when there is an extreme imbalance between number of the branes and antibranes, just as in the 2 $S^3$ case.

3.6. Brane/anti-Brane gauge system

It is natural to ask whether we can find a simple description of the non-supersymmetric theory corresponding to the brane/anti-brane system. This certainly exists in the full open string field theory. However, one may wonder whether one can construct a field theory version of this which maintains only a finite number of degrees of freedom. In fact, it is not clear if this should be possible, as we will now explain.

Consider a simpler situation where we have a stack of $N$ parallel D3 branes. This gives an $\mathcal{N} = 4$ supersymmetric $U(N)$ gauge theory. Now consider instead $(N + k)$ D3 branes and $k$ anti-D3 branes separated by a distance $a$. This is clearly unstable, and will decay back to a system with $N$ D3 branes. Can one describe this in a field theory setup? There have been attempts [18] along these lines (in connection with Sen’s conjecture [19]), however no complete finite truncation seems to exist. This system is similar to ours. In particular, consider the case with 2 $S^3$’s, with a total of $N$ D5 branes. We know that we can have various supersymmetric vacua of this theory in which

$$U(N) \to U(N_1) \times U(N - N_1)$$
where we have $N_1$ branes wrap one $\mathbf{P}^1$ and $N - N_1$ wrap the other. However we also know that the theory with $N$ D5 branes can come from a meta-stable vacuum with $(N + k)$ D5 branes wrap around one $\mathbf{P}^1$ and $k$ anti-D5 branes around the other. This theory would have a $U(N + k) \times U(k)$ gauge symmetry. Clearly we need more degrees of freedom than are present in the $U(N)$ theory in order to to describe this theory. In fact, since $k$ can be arbitrarily large, we cannot have a single system with a finite number of degrees of freedom describing all such metastable critical points. Of course, one could imagine that there could be a theory with a finite number of fields which describes all such configurations up to a given maximum $k$, but this does not seem very natural. It is thus reasonable to expect that string field theory would be needed to fully describe this system.

Nevertheless we have seen, to leading order, a very simple running of the two gauge groups in the non-supersymmetric case, and it would be natural to ask if we can explain this from the dual open string theory. In this dual theory, where we have some branes wrapping the first $\mathbf{P}^1$ and some anti-branes the other, we have three different types of sectors: the 1-1, 2-2 and the 1-2 open string sectors. The 1-1 and the 2-2 subsectors are supersymmetric and give rise to the description of the $\mathcal{N} = 1$ supersymmetric $U(N_i)$ theories for $i = 1, 2$, coupled to the adjoint matter fields $\Phi$ which are massive. This part can be inherited from the supersymmetric case, and in particular explains the fact that the running of the coupling constant of the $U(N_i)$ from the massive field $\Phi$ is the same as in the supersymmetric case. The difference between our case and the supersymmetric case comes from the 1-2 subsector. In the NS sector we have the usual tachyon mode whose mass squared is shifted to a positive value, as long as $\Delta$ is sufficiently larger than the string scale, due to the stretching of the open string between the far separated $\mathbf{P}^1$'s. We also have the usual oscillator modes. In the Ramond sector ground state the only difference between the supersymmetric case and our case is that the fermions, which in the supersymmetric case is the gaugino partner of the massive $W_{12}$ boson, has the opposite chirality. The fact that they have the opposite chirality explains the fact that the $\theta$ term of the gauge group runs with an opposite sign compared to the supersymmetric case. In explaining the fact that the norm runs the same way as the supersymmetric case, the contributions of the fermions is clear, but it is not obvious why the NS sector contribution should have led to the same kind of running. It would be interesting to explain this directly from the open string theory annulus computation in the NS sector.

It is easy to generalize the discussion above to the $n \ S^3$ case. In fact just as in the 2 $S^3$ case, the only subsectors which are non-supersymmetric are the $i - j$ sectors where
$i$ is from a brane and $j$ is from an anti-brane cut. This agrees with the results obtained in the general case, where supersymmetry breaking contributions come, to leading order, precisely from these sectors.

4. Decay Rates

In the previous sections, we constructed non-supersymmetric vacua of string theory corresponding to wrapping D5 branes and anti-D5 branes on the 2-cycles of the a local Calabi-Yau. Here, branes and anti-branes are wrapping rigid 2-cycles which are in the same homology class, but are widely separated, and there are potential barriers between them of tunable height. As we emphasized, the crucial aspect of this is that the vacua obtained in this way can be long lived, and thus are different from brane-anti brane systems in flat space, or systems of branes and anti-branes probing the Calabi-Yau manifold, which have been considered in the literature. Moreover, when the numbers of branes on each 2-cycle is large, this has a holographic dual in terms of non-supersymmetric flux vacua. By duality, we also expect the corresponding flux vacua to be metastable, despite breaking supersymmetry. In this section we will explore the stability of these vacua in more detail.

In both open and closed string language, the theory starts out in a non-supersymmetric vacuum. Since there are lower energy states available, the non-supersymmetric vacuum is a false vacuum. As long as the theory is weakly coupled throughout the process, as is the case here, the decay can be understood in the semi-classical approximation. This does not depend on the details of the theory, and we will review some aspects of the beautiful analysis in [20]. Afterwards, we apply this to the case at hand.

The false vacuum decays by nucleating a bubble of true vacuum by an instanton process. The rate of decay $\Gamma$ is given in terms of the action of the relevant instanton as

$$\Gamma \sim \exp(-S_I).$$

The instanton action $S_I$ is the action of the euclidean bounce solution, which interpolates between the true vacuum inside the bubble and the false vacuum outside of the bubble.\textsuperscript{10}

\textsuperscript{10} The coefficient of proportionality comes from the one loop amplitude in the instanton background, and as long as $S_I$ is large, its actual value does not matter.
Assuming that the dominant instanton is a spherical bubble of radius $R$, the euclidian instanton action is given by \[ \text{20} \]

$$S_I = -\frac{\pi^2}{2} R^4 \Delta V + 2\pi^2 R^3 S_D$$

The first term is the contribution to the action from inside the bubble. Here $\Delta V$ is the difference in the energy density between the true and the false vacuum, and this is multiplied by the volume of the bubble (a 4-sphere of radius $R$). The second term is the contribution to the action from the domain wall that interpolates between the inside and the outside on the bubble, assuming the domain wall is thin. There, $S_D$ is the tension of the domain wall, and $2\pi^2 R^3$ is its surface area (the area of a 3-sphere of radius $R$). The radius $R$ of the bubble is determined by energetics: The bubble can form when the gain in energy compensates for the mass of the domain wall that is created. The energy cost to create a bubble of radius $R$ is

$$E = -\frac{4\pi}{3} R^3 \Delta V + 4\pi R^2 S_D$$

where the first term comes from lowering the energy of the vacuum inside the bubble, and the last term is the energy cost due to surface tension of the domain wall. We can create a bubble at no energy cost of radius

$$R_* = 3 \frac{S_D}{\Delta V}.$$

Bubbles created with radii smaller than this recollapse. The bubbles created at $R = R_*$ expand indefinitely, as this is energetically favored. At any rate, the relevant instanton action is $S_I(R_*)$, or

$$S_I = \frac{27\pi}{2} \frac{S_D^4}{(\Delta V)^3}.$$ 

Correspondingly, the vacuum is longer lived the higher the tension of the domain wall needed to create it, and the lower the energy splitting between the true and the false vacuum.

With this in hand, let us consider the decays of the vacua we found. When the number of branes wrapping each $\mathbb{P}^1$ is small, the open string picture is appropriate. Consider, for simplicity, the case where the superpotential has only two critical points

$$W'(x) = g(x - a_1)(x - a_2),$$

36
and we have only a single brane at \( x = a_1 \) and a single anti-brane at \( x = a_2 \). The effective potential that either of these branes sees separately is given simply by the size of the 2-sphere it wraps
\[
A(x) = (|W'(x)|^2 + |r|^2)^{1/2}
\] (4.1)
where \( |r| \) is the tension of the brane wrapping the minimal \( \mathbb{P}^1 \) (see section 3). The branes are, of course, also charged, so there is an electric field flux tube (of the six-form potential) running between the brane and the anti-brane, along a 3-cycle corresponding to an \( S^2 \) being swept from \( x = a_1 \) to \( x = a_2 \). Despite the flux tube, the system is (meta)stable if the potential barrier from (4.1) is high enough. The decay process corresponds, for example, to having the D5-brane tunnel under the energy barrier from the vacuum at \( x = a_1 \) to the vacuum \( x = a_2 \), to annihilate with the anti-D5-brane there. More precisely, what happens is that a bubble of true vacuum is created in \( R^{3,1} \), inside of which the branes are annihilated. The boundary of the bubble is a domain wall which, in the thin wall approximation, corresponds to a D5 brane wrapping the \( S^2 \) boundary of the bubble in \( R^3 \) and the 3-cycle in the Calabi-Yau where the flux tube was. The tension of the domain wall is the the size of the 3-cycle that the D5 brane wraps in the Calabi-Yau times the tension of the 5-brane
\[
S_D = \frac{1}{g_s} \int_{a_1}^{a_2} A(x) dx \approx \frac{1}{g_s} |W(a_2) - W(a_1)| = \frac{1}{3g_s} |g\Delta^3|
\]
where the second term in (4.1) gives vanishingly small contribution in the limit \( \Delta \gg r \).

The difference in the cosmological constants of the two vacua corresponds, to the leading order, to the difference in tensions between the original configuration, with \( V_i = 2|r|/g_s \) and the final one where the branes have annihilated \( V_f = 0 \), so the gain in energy is simply
\[
\Delta V = 2 \frac{|r|}{g_s} = \frac{2}{g_s^2} \frac{g^3}{Y_M}
\]

When the number of branes wrapping the \( \mathbb{P}^1 \)'s is large, we use the dual geometry from after the transition, with fluxes. Consider, for example, the case when \( N_1 \) branes wraps the first \( \mathbb{P}^1 \) and \( |N_2| \) anti-branes the second, with \( |N_{1,2}| \) large, and satisfying
\[
N_1 > 0 > N_2.
\]

\footnote{For us, the mass of the brane comes from the B-field only, and the brane is heavy only because the string coupling is weak.}
Then, the $C$ cycle that runs between the two cuts, $[C] = [B_1] - [B_2]$ is a compact flux tube, with $|N_2|$ units of $H^{RR}$ flux running through it. To decay, one kills off the flux lines one by one, by creating an D5 brane wrapping a zero size $\mathbb{P}^1$ where the first $\mathbb{P}^1$ used to be before the transition. This brane grows and eats up the flux line until it vanishes again at the first cut. After all the flux has decayed, this leaves us with $N_1 + N_2$ units of flux through the first $S^3$. The tension of the corresponding domain wall is

$$S_D = \frac{|N_2|}{g_s} \int_C |\Omega|$$

where

$$\oint_C \Omega = \int_{B_1} \Omega - \int_{B_2} \Omega \approx W(a_2) - W(a_1).$$

where we omit terms that are exponentially suppressed in the vacuum. In this case, the energy of the false vacuum is, to the leading order, $V_i = (|N_1| + |N_2|)|r|/g_s$. After the flux has decayed, we have $V_f = (|N_1| - |N_2|)|r|/g_s$ coming from the flux through first $S^3$ only. The difference is just

$$\Delta V = V_i - V_f \approx 2|N_2| \frac{|r|}{g_s} = \frac{2|N_2|}{g^2_{YM}}$$

We see that both the domain wall tension and the difference in vacuum energies before and after are equal to what we found in the open string picture, albeit rescaled by the amount of brane charge which disappears! This is, of course, not surprising because the domain wall relevant in the closed string case is the same one as that relevant in the open string case, just before the large $N$ transition.

We can now put everything together to compute the action of the instanton corresponding to nucleating a bubble of true vacuum:

$$S_I \approx \frac{\pi}{48} \frac{|N_2|}{g_s} \left|\frac{(g\Delta^3)^4}{|r|^3}\right|.$$

This leads to the decay rate

$$\Gamma \sim \exp(-S_I).$$

Note that the relevant instantons come from D-branes wrapping cycles, and thus it is natural for the instanton action to depend on $g_s$ in the way the D-brane action does.

---

12 More precisely, we should evaluate the corrections to this at the values of $S_{1,2}$ corresponding to being somewhere in the middle between the true and the false vacuum. Either way, the omitted terms are suppressed by, at least, $\frac{\Lambda_{1,2}}{\Delta}$, and we can neglect them.
This exactly reproduces the results one would have expected from our discussion in section 3. There are two effects controlling the stability of the system. Namely, one is the height of the potential barrier, which is controlled by here by \( g \Delta^3 \) and which enters the action of the domain wall. The branes and anti-branes become more separated the larger the \( \Delta \), and their interactions weaker. In addition, increasing the height of the potential barrier by making \( \Delta \) larger, overcomes the electrostatic attraction of the branes. The other relevant parameter is the relative difference in energies of the true and the false vacuum, which depends on the ratio of brane to anti-brane numbers \( |N_2/N_1| \). When this is very small, the vacuum with both the branes and the anti-branes is nearly degenerate with the vacuum with just the branes, and correspondingly, the decay time gets longer as \( \Delta V/V \) gets smaller.

5. Open Questions

In this paper, we have seen how a large \( N \) system of branes which geometrically realizes metastability by wrapping cycles of a non-compact CY can be dual to a flux compactification which breaks supersymmetry. We provided evidence for this duality by studying the limit where the cycles of the Calabi-Yau are far separated.

There are a number of open questions which remain to be studied: It would be nice to write down a non-supersymmetric gauge theory with finite number of degrees of freedom which describes this brane configuration. It is not clear that this should be possible, but it would be interesting to settle this question conclusively one way or the other. This is also important for other applications in string theory where dynamics of brane/anti-brane systems is relevant.

Another issue which would be important to study is the phase structure of our system. Since we have broken supersymmetry, we have no holomorphic control over the geometry of the solutions. It would be interesting to see what replaces this, and how one should think of the global phase structure of these non-supersymmetric solutions. Since the full potential is characterized by the \( \mathcal{N} = 2 \) prepotential and the flux data, which in turn are characterized by integrable data (matrix model integrals of the superpotential), one still expects that the critical points of the potential should be characterized in a nice way. Understanding this structure would be very important. For example, it would tell us what happens when the separation of the wrapped cycles is small where one expects to lose metastability due to the open string tachyons stretching between branes and anti-branes.
One other issue involves the $1/N$ corrections to the holographic dual theory. In this paper we have focused on the leading order in the $1/N$ expansion, i.e. at the string tree level. How about subleading corrections? This is likely to be difficult to address, as one expects non-supersymmetric corrections to string tree level to be difficult to compute. The fact that we have a metastable system suggests that we would not want to push this question to an exact computation, as we know the system is ultimately going to decay to a stable system. However, we would potentially be interested in studying the regions of phase space where metastability is just being lost, such as when the cycles are close to one another.

Finally, perhaps the most important question is about the embedding of our mechanism for inducing metastable flux compactification vacua into a compact Calabi-Yau geometry (see [21]). At first sight, it may be unclear whether there would be any obstacles to a compact embedding of our story. There is at least an example similar to what we are expecting in the compact case. In [22], among the solutions studied, it was found that flipping the signs of some fluxes leads to apparently metastable non-supersymmetric vacua. It would be interesting to see if this connects to the mechanism introduced in this paper, where the existence of metastability for flux vacua is a priori expected. Moreover, from our results it is natural to expect that most flux vacua do have metastable non-supersymmetric solutions. For instance, in the non-compact case we have studied, only 2 out of $2^n$ choice of signs for the $n$ fluxes were non-supersymmetric. This suggests that in the study of flux compactifications, the most natural way to break supersymmetry is simply studying metastable vacua of that theory, without the necessity of introducing any additional anti-branes into the system. It would be very interesting to study this further.

Acknowledgments

We would like to thank N. Arkani-Hamed, K. Becker, M. Becker, R. Bousso, E. Imeroni, K. Intriligator, K. Kim, J. McGreevy, L. Motl, D. Sahakyan, D. Shih, W. Taylor and B. Zwiebach for valuable discussions. We would also like to thank the Stony Brook Physics department and the fourth Simons Workshop in Mathematics and Physics for their hospitality while this project was initiated.
