Complex refractive indices in the near-ultraviolet spectral region of biogenic secondary organic aerosol aged with ammonia

Atmospheric absorption by brown carbon aerosol may play an important role in global radiative forcing. Brown carbon arises from both primary and secondary sources, but the mechanisms and reactions of the latter are highly uncertain. One proposed mechanism is the reaction of ammonia or amino acids with carbonyl products in secondary organic aerosol (SOA). We generated SOA in situ by reacting biogenic alkenes (α-pinene, limonene, and α-humulene) with excess ozone, humidifying the resulting aerosol, and reacting the humidified aerosol with gaseous ammonia. We determined the complex refractive indices (RI) in the 360–420 nm range for these aerosols using broadband cavity enhanced spectroscopy (BBCES). The average real part (n) of the measured spectral range of the NH3-aged α-pinene SOA increased from n = 1.50 (±0.01) for the unreacted SOA to n = 1.57 (±0.01) after 1.5 h of exposure to 1.9 ppm NH3, whereas the imaginary component (k) remained below k < 0.001 (±0.001). For the limonene and α-humulene SOA the real part did not change significantly, and we observed a small change in the imaginary component of the RI. The imaginary component increased from k = 0.000 to an average k = 0.029 (±0.021) for α-humulene SOA, and from k < 0.001 (±0.001) to an average k = 0.032 (±0.019) for limonene SOA after 1.5 h of exposure to 1.3 and 1.9 ppm of NH3, respectively. Collected filter samples of the aged and unreacted α-pinene SOA and limonene SOA were analyzed off-line by nanospray desorption electrospray ionization high resolution mass spectrometry (nano-DES/HR-MS), and in situ using a Time-of-Flight Aerosol Mass Spectrometer (ToF-AMS), confirming that the SOA reacted and that various nitrogen-containing reaction products formed. If we assume that NH3 aging reactions scale linearly with time and concentration, which will not necessarily be the case in the atmosphere, then a 1.5 h reaction with 1 ppm NH3 in the laboratory is equivalent to 24 h reaction with 63 ppbv NH3, indicating that the observed aerosol absorption will be limited to atmospheric regions with high NH3 concentrations.

1. Introduction

Atmospheric aerosols play an important role in the Earth’s radiative budget by absorbing and scattering solar radiation and by influencing cloud properties. Light-absorbing aerosols (including black carbon, mineral dust, and brown carbon) are recognized to have a potentially important role in climate radiative forcing. Atmospheric brown carbon (BrC) refers to light-absorbing organic particulate matter, which can be generated both from primary sources (e.g., combustion, biomass burning, soil humics, bioaerosols) and from secondary organic reactions (e.g., particle or aqueous-phase reactions). The interest and climatic importance of BrC aerosol are due to the strong dependence of its absorption on its composition, the complexity of its production mechanisms, and the poor constraints on its contribution to radiative forcing. Only recently, studies have shown that brown carbon aerosol may account for 10 to 50% of the total light absorption in the atmosphere, snow, and sea ice.

Primary emissions of BrC have been observed in wildfire events, residential coal combustion, and release of biological aerosols (for example, fungi, plant debris, and humic matter). In addition to primary emissions, BrC compounds may occur in
secondary organic aerosol (SOA) consisting of high molecular weight and multifunctional species, such as humic-like substances, organonitrates, and organosulfates. The principal precursors, mechanisms, and products in the formation of secondary BrC are poorly known, and different reactions and mechanisms have been proposed to explain the light absorption by secondary organic aerosol:

1. Reaction of ammonia (NH₃) or amino acids with secondary organic aerosol that contains carbonyl products.20–23 This category of reactions may further include aqueous reactions of glyoxal and methylglyoxal with ammonium sulfate,24–28 aqueous reactions between glyoxal and amino acids,24,26,29 and gas-to-particle uptake of glyoxal by deliquesced AS and amino acid-containing aerosol.30–33 A proposed mechanism for the ammonia reaction with carbonyls starts with conversion of protonated carbonyls into primary imines and amines (R1a), which then react with additional carbonyls to produce more stable secondary imines (R1b) and heterocyclic (R1c) nitrogen containing compounds. The products of these reactions may continue to react with unreacted carbonyl groups yielding higher molecular weight molecules with an extended network of conjugated bonds:21

\text{R}_1 & \text{H}^+ \quad \text{H}_2\text{O} \\
\text{R}_1 \quad \text{H}^+ \quad \text{H}_2\text{O} \\
\end{align*}
\]

(2) Acid-catalyzed aldol condensation of volatile aldehydes,34–41 which is only expected to be important under H₂SO₄ concentrations characteristic of stratospheric aerosols.

(3) Nitration of polycyclic aromatic hydrocarbons (PAH) leading to light absorbing nitro-PAH, and their derivatives such as nitrophenols.42–45

(4) Other proposed mechanisms such as reaction of OH radicals with aromatic hydroxyacids and phenols in cloud water,46–49 heterogeneous reactions of gas-phase isoprene on acidic aerosol particles,50 and aqueous photochemistry of pyruvic acid in the presence of common atmospheric electrolytes (e.g., SO₂⁻, NH₄⁺).51,52

The majority of the studies summarized above use bulk solution-phase reactions to simulate aerosol-aging mechanisms. It is critical to study this chemistry in situ by realistic aerosol size distributions, as bulk-phase reactions may be limited by the rate of transport of gaseous reactants and products in and out of the condensed phase. Furthermore, in situ measurements are necessary to evaluate the influence of aging mechanisms on aerosol optical properties as they may occur in the atmosphere. SOA optical extinction and refractive indices at selected wavelengths in the UV and visible spectral regions have been measured in the laboratory,53–64 with a few measurements throughout the visible spectrum.53,55,64 Recent advances in broadband cavity enhanced spectroscopy (BBCES) allow aerosol optical extinction, optical cross section, and the real (scattering) and imaginary (absorption) components of the refractive index to be determined as a function of wavelength.65–67 Here, we use the instrument described in Washenfelder et al. (2013)65 to measure optical properties in the near-UV spectral region of SOA formed by the reaction of biogenic alkenes with ozone, and by subsequent reaction with NH₃.

Based on the study by Updyke et al. (2012)23 we select biogenic alkenes that form SOA that can undergo different degrees of “browning” (i.e., a visible change in color or measured absorption spectrum) upon exposure to NH₃. In each case, we measure the aerosol optical extinction coefficient and cross section, and we use these quantities to retrieve the refractive index before and after SOA reactions with gas-phase NH₃. We compare our results to the imaginary part of the refractive index determined by ultraviolet/visible (UV/Vis) absorption of solution-phase products, and assess the climatic importance using the “simple forcing efficiency” (SFE) defined by Bond and Bergstrom (2006).68

2. Experimental

2.1. Generation of NH₃-aged biogenic SOA

The flow system for aerosol generation and aging is shown schematically in Fig. 1A and described in detail below. SOA was generated by ozonolysis of three different biogenic alkenes: α-pinene, limonene and α-humulene. The liquid volatile organic compound (VOC) was injected using a syringe pump at 0.7–4.1 µL h⁻¹ into a N₂ carrier gas flow of 0.4 volumetric liters per minute (vLpm). O₃ was generated by passing 0.1 vLpm of moisture-free O₂ through a commercial Double-Bore UV lamp (Jelight Company Inc., Irvine, CA, USA). The two flows were combined in a 10 L bulb, to give an initial VOC concentration of ~10 parts per million by volume (ppmv) for the upper limit infusion rate from the syringe pump. The O₃ mixing ratio was measured to be 90 (~±10) ppm using a commercial O₃ monitor (Model 1180, Dasibi Environmental Corp., Glendale, CA, USA). The ozone + VOC reaction took place under dark conditions. After the reaction bulb, an ozone denuder (Carulite 200; Carus Corp., Peru, IL, USA) removed the residual O₃ from the sample flow. The SOA flow was then humidified to 85% relative humidity (RH) using a Nafion humidifier (PermaPure LLC, Toms River, NJ, USA) with a temperature-controlled bath. BrC formation upon exposure to NH₃ has only been observed under humid conditions (RH ~ 85%).21 The humidified SOA was introduced to a 30 L flow tube where it was combined with gaseous NH₃ and allowed to react for 1.5 h. The SOA was then dried to <10% RH using a diffusion dryer and the residual NH₃ was removed using silicon phosphate pellets (AS-200-08-E, Perma Pure LLC., Toms River, NJ, USA), before being size-selected using a differential mobility analyzer (DMA; Model 3081, TSI Inc., Shoreview, MN, USA). The size-selected aerosol
was introduced to the two BBCES cells in series and finally counted using a condensation particle counter (CPC; Model 3775, TSI Inc., Shoreview, MN, USA). For measurements without NH₃, the SOA was passed through the same setup without the addition of NH₃ in the 30 L bulb. The reaction time in the bulb was sufficient to generate a stable aerosol population of VOC oxidation products, with the mode diameter typically near 200 nm and total mass concentrations of 1100 (±100) μg m⁻³.

NH₃ gas was generated by bubbling 0.005 to 0.04 vppm N₂ through a 10 mM NH₄OH solution. The NH₃ concentration was measured using an NH₃ detector (Model TX-2460DP-D, Bionics Instrument Co. Ltd., Tokyo, Japan) before it entered the 30 L flow tube to react with the humidified SOA. To control the concentration of ammonia that was introduced into the flow tube, and to determine the residence time, a constant total flow of 0.3 vppm was maintained in the flow tube throughout the experiments. By changing the N₂ flow through the NH₄OH solution, different NH₃ concentrations were introduced while maintaining the same total flow in the system. The relative humidity of the NH₃ flow varied between 70% at 0.005 vppm and 86% at 0.04 vppm, resulting in a relative humidity for the total aerosol flow of 85% ± 2%.

2.2. Broadband cavity enhanced extinction spectroscopy (BBCES)

The BBCES technique employs a broadband light source, a high-finesse optical cavity, a grating spectrometer and a multichannel detector to simultaneously determine optical extinction across a broad wavelength region. Initial measurements demonstrated its potential to measure the optical extinction of ambient aerosol and recent studies have demonstrated how the technique may be combined with aerosol size-selection to determine aerosol extinction cross sections and refractive indices as a function of wavelength.

The optical instrument used in this study consists of two channels to measure aerosol optical extinction from 360 to 390 nm and 390 to 420 nm, respectively. It is similar to the instrument described in detail in Washenfelder et al. (2013) and briefly summarized here. Fig. 1B shows a schematic of the BBCES system used in this study.

Light emitting diodes (LEDs) centered at 370.2 and 407.1 nm with measured optical power outputs of 0.210 W and 0.450 W (NCSU033A, Nichia Corp., Tokyo, Japan; LZ1-00UA05, LEDEngin Inc., San Jose, CA, USA) are temperature-controlled and powered by a constant-current power supply to achieve a stable optical power output. The output from each LED is collimated using a single F/1.2 fused silica lens into an optical cavity formed by two 2.5 cm, 1 m radius of curvature mirrors (Advanced Thin Films, Boulder, CO, USA). The measured mirror reflectivity for the two cavities was typically 0.9995 and 0.99994 at 370 and 407 nm, respectively. The light entering the cavity is optically filtered using bandpass filters (FGUV5 and FB400-40, Thorlabs, Newton, NJ, USA).
After exiting each cavity, the light is directly collected using a 0.1 cm F/2 fiber collimator (74-UV, Ocean Optics, Dunedin, FL, USA) into one lead of a two-way 100 μm core HOH-UV-VIS fiber (SR-OPT-8015, Andor Technology, Belfast, UK) which is linearly aligned along the input slit of the grating spectrometer.

Spectra were acquired using a 163 mm focal length Czerny-Turner spectrometer (Shamrock SR-163, Andor Technology, Belfast, UK) equipped with a charge coupled device (CCD) detector (DU920P-BU, Andor Technology, Belfast, UK) maintained at −50 °C. The installed 300 grove mm⁻¹ (500 nm blaze) grating allows spectral measurements over the region 101–621 nm, although only a portion of that spectral region was used in these experiments. The spectrometer is temperature-controlled at 32.0 °C. Dark spectra were acquired using the input shutter (SR1-SHT-9003, Andor Technology, Belfast, UK) closed prior to each set of spectra. The wavelength calibration was determined using a Hg/Ar pen-ray lamp. The 100 μm fiber from each measurement channel illuminated separate vertical regions of the CCD, which were digitized to produce two spectra.

The general expression that relates the extinction coefficient by aerosols, \( \varepsilon (\lambda) \) measured in cm⁻¹, in an N₂-filled cavity, to the change in intensity of the transmitted light is given by:

\[
\varepsilon_{\text{ext}} (\lambda) = R_L \left( \frac{1 - R(\lambda)}{d} + \varepsilon_{\text{Rayleigh}} N_2(\lambda) \right) \frac{(I_{0}(\lambda) - I(\lambda))}{I(\lambda)}
\]

where \( R_L \) is the ratio of the total length \( d \) to the filled length of the cavity, \( R(\lambda) \) is the mirror reflectivity, \( \varepsilon_{\text{Rayleigh}} N_2(\lambda) \) is the extinction coefficient due to Rayleigh scattering by N₂, \( I_{0}(\lambda) \) is the spectrum \( (i.e., \text{the wavelength-dependent intensity transmitted through the cavity and imaged to the CCD}) \) of N₂, and \( I(\lambda) \) is the spectrum with aerosol and N₂ present. Using the particle number concentration \( (N) \) measured by the CPC, the optical extinction cross section, \( \sigma(\lambda) \) measured in cm², at each wavelength can be calculated:

\[
\sigma_{\text{ext}} (\lambda) = \frac{\varepsilon_{\text{ext}} (\lambda)}{N}
\]

For spherical particles, the measurement of several diameters allows the retrieval of the complex refractive index at each wavelength by minimizing the expression

\[
\chi^2 (\lambda) = \sum_{i=1}^{N_p} \left( \frac{\sigma_{\text{measured}} (\lambda) - \sigma_{\text{ext,calculated}} (\lambda)}{\sigma_{\text{measured}} (\lambda)} \right)^2
\]

where \( N_p \) is the number of diameters measured and \( \sigma_{\text{ext,calculated}} \) is the theoretical optical cross section calculated using Mie theory by varying the real \( (n) \) and imaginary \( (k) \) components of the complex refractive index \( (\text{RI}) \). We account for the contribution of multiply-charged particles by calculating the size distribution exiting the DMA for each diameter using DMA transfer theory and steady-state charge distribution approximation.

2.3. Operational details for in situ generation and sampling

The aerosol generation, including VOC, O₃, and NH₃ flows, temperatures, and other components, were allowed to stabilize for at least 1 h prior to each set of measurements. A scanning mobility particle sizer (SMPS) was used to verify that the aerosol size distribution was stable prior to the measurements. After the aerosol size distribution stabilized, an SMPS scan was taken for multiple-charge correction while the BBCEES reflectivity term in eqn (1) was determined by recording spectra with the cavity filled by He and N₂ sequentially. Next, a zero-particle measurement was performed followed by measurements with a series of size selected particles, typically in the range of \( D_p = 200–450 \text{ nm} \) in 50 nm increments. After the size-selection measurements, another zero-particle, reflectivity and size distribution measurement was performed. Measurements with polystyrene latex spheres (PSL) of known sizes were performed to evaluate the performance of the experimental setup before or after each experiment.

2.4. UV/Visible absorption spectroscopy

In addition to the in situ generation of aerosol and measurement of optical extinction described above, we used a UV/Vis spectrometer (Cary 100 UV-Vis, Agilent Technologies Inc., Santa Clara, CA, USA) to measure absorption by aerosols dissolved in aqueous solution. Besides the refractive index, another standard metric of aerosol absorption in the UV/Vis region is the mass absorption coefficient (MAC), given in units of m² g⁻¹:

\[
\text{MAC} (\lambda) = \frac{A(\lambda) \ln(10)}{C b}
\]

where \( A(\lambda) \) is the base-10 absorbance measurement (unitless), \( C \) is the concentration of the liquid solution (g m⁻³), and \( b \) is the sample path length (m). The relationship between \( k \) and the MAC is

\[
\text{MAC} = \frac{4 \pi k}{\rho_{\text{material}}} \cdot
\]

where \( \rho_{\text{material}} \) is the density of the organic material. For our measurements, we assume a density of 1.4 g cm⁻³, which is a recommended value for biogenic SOA. UV/Vis absorption spectroscopy cannot be used to determine the real part of the refractive index. For an assumed density of 1.4 g cm⁻³ and a wavelength of 400 nm, a \( k \) value of 0.01 corresponds to MAC = 0.22 m² g⁻¹, while a \( k \) value of 0.05 corresponds to MAC = 1.12 m² g⁻¹.

2.5. Analysis of aerosol composition

We used two methods to determine the chemical composition of the in situ aerosol described above: Time-of-Flight Aerosol Mass Spectrometry (ToF-AMS) and nanospray Desorption Electrospray Ionization High Resolution Mass Spectrometry (nano-DESI/HR-MS).

ToF-AMS. For α-pinene and limonene, we generated SOA and aged the aerosol with 1 ppmv of NH₃, as described in Section 2.1. We analyzed in situ both NH₃-aged and unreacted α-pinene and limonene SOA using a ToF-AMS (Aerodyne Research, Inc., Billerica, MA, USA) connected directly to the experimental setup. A detailed description of the ToF-AMS can be found in DeCarlo et al. (2006). The ToF-AMS operated in the more sensitive V-mode ion path with the results presented here obtained using the mass spectrum (MS) mode (in which the ion signals are integrated over all particle sizes). Data analysis of the MS was done using Squirrel v.1.51H.
Nano-DESI/HR-MS. We collected filter (Whatman 2 μm PTFE 46.2 mm 7592-104, Whatman Inc., Florham Park, NJ, USA) samples of limonene SOA and α-pinene SOA, before and after aging by NH₃. The filters were analyzed using a high-resolution LTQ-Orbitrap MS (Thermo Fisher, Bremen, Germany) equipped with a nano-DESI source, following by assignment of molecular formulae to the observed peaks using the procedure described in Roach et al. (2011). The instrument was operated in the positive-ion mode with a resolving power of 100 000 at m/z 400, and calibrated using a standard calibration mixture (Calibration mix MSCAL 5, Sigma-Aldrich Co. LLC, St. Louis, MO, USA). A voltage of 3–4 kV was applied between the capillary end and the mass spectrometer inlet to obtain a stable spray of charged droplets. The solvent (acetonitrile/water mixed at 70/30 volumetric ratio) was supplied at a 2–3 μl min⁻¹ flow rate to maintain a stable nano-DESI probe on the sample surface.

2.6. Radiative impact

To estimate the direct radiative forcing in watts per gram, Bond and Bergstrom (2006) modified the forcing equation of Chylek and Toomey (2006) to provide an estimate of the radiative impact of the aged SOA:

\[
\frac{d\text{SFE}}{d\lambda} = -\frac{1}{4} \frac{dS(\lambda)}{d\lambda} \tau_{\text{atm}}^2(\lambda)(1 - F_c) [2(1 - a_s)^2 \beta(\lambda) \cdot \text{MSC}(\lambda) - 4a_s \cdot \text{MAC}(\lambda)]
\]

where \(dS(\lambda)/d\lambda\) is the solar irradiance, \(\tau_{\text{atm}}\) is the atmospheric transmission, \(F_c\) is the cloud fraction (0.6), \(a_s\) is the surface albedo (average of 0.19), \(\beta\) is the backscatter fraction, and MSC is the mass scattering.

3. Results and discussion

3.1. Refractive indices of NH₃-aged biogenic SOA measured in situ by BBCES

The reaction of each biogenic VOC with O₃ for 20 min produced stable SOA size distributions. During the 1.5 h reaction of these aerosols with NH₃, this size distribution shifted to larger diameters and the number of particles decreased, which can be attributed to coagulation and loss of the particles to the walls of the flow tube.

The retrieved complex refractive indices are shown in Fig. 2 as a function of wavelength between 360 and 420 nm for the three different SOA. The biogenic alkenes are arranged in the order of increasing absorption for their NH₃-aged SOA, based on the study of Updyke et al. (2012). Refractive indices of α-pinene SOA and its aging at three NH₃ concentrations (0.3 ppm, 1.0 ppm, and 1.9 ppm) are shown in Fig. 2A. There is no detectable absorption for the α-pinene SOA, with an average imaginary component over the 360–420 nm range of \(k < 0.001 \pm 0.002\) even after 1.5 h of aging with 1.9 ppm of NH₃. However, there is an increase in the real part of the RI, from an average \(n = 1.50 \pm 0.01\) to \(n = 1.53 \pm 0.02\) with the addition of 0.3 ppm NH₃, and a greater increase up to an average \(n = 1.57 \pm 0.01\) with 1.9 ppm NH₃. The increase might be attributed to an increase in the density of the aerosol. The α-humulene SOA in Fig. 2B shows no increase in the real part of the RI, but the imaginary component increases to an average value of \(k = 0.029 \pm 0.021\) at NH₃ concentration greater than 1.0 ppm. The limonene SOA in Fig. 2C similarly shows that the real part of the RI remains constant at all NH₃ concentrations, and there is a small increase in the imaginary component of the RI (\(k = 0.032 \pm 0.019\)) when the aerosol is aged with 1.9 ppm NH₃. The refractive indices of all of these SOA show a wavelength-dependent real part between 1.47 and 1.59 and an imaginary part less than 0.07. The error bars in Fig. 2 were calculated by scaling the measured extinction cross sections by the total measurement uncertainty (<4%).

The BBCES measurements and retrieved refractive indices indicated minor or no detectable absorption by the in situ NH₃-aged aerosol with [NH₃] < 1.0 ppm in the 360–420 nm range. To understand this result, we undertook a series of additional experiments described in Sections 3.2–3.4. First, we used the BBCES to measure refractive indices of atomized Suwannee River Fulvic Acid (SRFA) and atomized NH₃-aged limonene SOA samples generated in a different laboratory (Section 3.2). Second, we used UV/Vis absorption spectroscopy to determine the absorption of SRFA and NH₃-aged aerosol in aqueous solution (Section 3.3). Finally, we analyzed the chemical composition of the NH₃-aged aerosol generated in our laboratory using nano-DESI/HR-MS and ToF-AMS to verify that the expected chemical products had been formed.

3.2. Refractive indices of atomized samples measured by BBCES

We measured extinction cross sections of aerosolized SRFA material (1S101F International Humic Substances Society, Saint Paul, MN, USA), which is often used as a proxy for brown carbon, to verify that there were no errors with the instrumental method or the refractive index retrieval, and to confirm the small absorption values determined for the NH₃-aged SOA. The aerosol was generated by atomizing an aqueous SRFA solution followed by drying and size selection. The retrieved RI values are shown in Fig. 3A, with a clearly-detectable absorption having an average retrieved value of \(k = 0.046 \pm 0.010\) in the 360–420 nm spectral region, consistent with previous work.

We measured an atomized aerosol from a filter sample of NH₃-aged limonene SOA that was generated at the University of California, Irvine by bubbling O₃ gas through an acetonitrile solution containing limonene at room temperature until all double bonds were consumed. Then an aqueous solution of ammonium sulfate was added, and the mixture was evaporated to produce an orange-colored residue. The organic fraction was extracted with acetonitrile and dried for storage and shipment. Oxidation of limonene in a non-participating solvent such as acetonitrile is expected to produce a similar set of products as in the gas-phase oxidation of limonene. The optical properties of the resulting SOA material were slightly different to that of limonene SOA aged by the method described in Updyke et al. (2012). The UC
Irvine filter sample was dissolved in acetonitrile and water, and atomized for measurement with the BBCES using the size-selection procedure and RI retrieval. Fig. 3A shows that for the aerosol there was no detectable absorption in the 360–420 nm range, with a retrieved \( k \) value equal to zero \( \pm 0.022 \) within experimental uncertainties, consistent with the results for the \textit{in situ} \( \text{NH}_3 \)-aged limonene SOA with lower \( \text{NH}_3 \) concentrations generated in our laboratory.

3.3. Refractive indices of \( \text{NH}_3 \)-aged biogenic SOA measured by UV/Vis spectroscopy

The atomization of the filter samples described in Section 3.2 showed that the \( \text{NH}_3 \)-aged biogenic SOA was much less absorbing than SRFA at 360–420 nm. We used UV/Vis absorption spectroscopy to measure and compare the absorption of three aqueous samples: SRFA, \( \text{NH}_3 \)-aged limonene SOA generated at UC Irvine, and \( \text{NH}_3 \)-aged limonene SOA generated using the flow tube system shown in Fig. 1 with \( \sim 1 \) ppmv \( \text{NH}_3 \) and collected on a filter for approximately 6 h.

For the UV/Vis spectra, the SRFA was dissolved in nanopure water, UC Irvine \( \text{NH}_3 \)-aged limonene SOA was dissolved in acetonitrile \((\text{CH}_3\text{CN})\), and the Weizmann Institute \( \text{NH}_3 \)-aged limonene SOA in nano-pure water and methanol. We prepared three mass concentrations for each of the three materials. Fig. 3B shows that both filter samples of \( \text{NH}_3 \)-aged limonene SOA are an order of magnitude less absorbing than SRFA. The \( \text{NH}_3 \)-aged limonene SOA from Updyke \textit{et al.} (2012)\textsuperscript{23} (see their Fig. 4) is also overlaid for comparison. It is also an order of magnitude less absorbing than SRFA in the 360–420 nm range and 31\% less absorbing at the peak seen around 500 nm. This is consistent with our BBCES \textit{in situ} measurements of the atomized filter samples which showed that SRFA was more strongly absorbing than \( \text{NH}_3 \)-aged limonene SOA (Section 3.2) and with the refractive index retrievals for the \textit{in situ} \( \text{NH}_3 \)-aged SOA. To directly compare the results from the UV-Vis and the
atomized and in situ BBCES measurements of the NH$_3$-aged limonene SOA, Fig. 3C shows calculated $k$ values from the MAC values shown in Fig. 3B (using eqn (5) and assuming a $\rho_{\text{material}} = 1.4 \, \text{g cm}^{-3}$), and the retrieved imaginary parts from the atomized and in situ BBCES measurements. Fig. 3C further shows the consistency of the UV-Vis and our BBCES in situ measurements. Based on the in situ BBCES measurements and the UV/Vis spectroscopy, we conclude that the NH$_3$-aged biogenic samples, although light orange in color, are substantially less absorbing than SRFA when normalized per unit mass of the material, in the measured wavelength region and under our experimental conditions.

Filter samples of $\alpha$-pinene and limonene SOA before and after NH$_3$-aging were collected as described above and also
examined visually. Filter samples of α-pinene SOA appeared white, with or without NH₃-aging. Filter samples of unreacted limonene SOA also appeared white, while limonene SOA that was exposed in situ to ∼ 1 ppmv NH₃ for 1.5 h was light orange in color, confirming that the NH₃ exposure caused visible changes in the optical properties of the aerosol. The light orange color does not arise from absorption in the 360–420 nm range, and is likely the result of absorption near 500 nm.

3.4. Composition of NH₃-aged biogenic SOA measured by nano-DESI/HR-MS and ToF-AMS

Nano-DESI-HRMS analysis. The chemical aging of limonene SOA and α-pinene SOA by NH₃ has been previously reported.²¹–²³,⁸⁴ Fig. 4 shows a histogram of the number of N and O atoms from the identified peaks in the nano-DESI/HR-MS spectra of the α-pinene SOA and limonene SOA with and without aging by NH₃. In Fig. 4A and B, the unreacted α-pinene SOA and limonene SOA spectra show that >96% of the fragments contain zero N atoms and <4% of the fragments contain one N atom. The species with one N atom likely originate from trace amounts of NH₃ emitted by the walls of the flow tube or are introduced during SOA sample handling from ammonia in ambient air. The unreacted SOA is mainly composed of organic molecules containing C, H, and O atoms. In contrast, the NH₃-aged samples show a significant increase in the fraction of organic constituents with one or two N atoms (1N and 2N, respectively). For NH₃-aged α-pinene SOA, the sample contained 26% and 2% of 1N and 2N species, respectively, while the NH₃-aged limonene SOA contained 12% and 5% of 1N and 2N species. The increase in nitrogen-containing species is accompanied by a shift in the distribution of oxygen atom

containing species toward molecules with a lower number of oxygen atoms. The change in the distribution of the number of N and O atoms for the limonene SOA observed in this study is similar to that of Laskin et al. (2010)²¹ observed for limonene SOA aged with NH₃ on a filter.

Laskin et al. (2010) proposed that condensation reactions associated with a substantial increase in the Double-Bond-Equivalent (DBE) values of neutral molecules are responsible for the formation of light-absorbing products. DBE values were determined from the elemental formulae of the identified peaks as described by Laskin et al. (2010)²¹ (see their eqn (3)). Fig. 5 compares the DBE vs. m/z for the aged and unreacted α-pinene SOA and limonene SOA. The DBE values of the unreacted and aged α-pinene SOA samples show a small difference between them; whereas the DBE values for the aged limonene SOA show a more significant difference in the 250–550 m/z range from the unreacted limonene SOA and both α-pinene SOA samples. These highly conjugated species also appeared in the same range of m/z in the Laskin et al. (2010)²¹ limonene SOA samples, and are potentially responsible for the orange color observed in the aged limonene SOA filter.

ToF-AMS analysis. Using a ToF-AMS, we measured the mass spectra of α-pinene and limonene SOA, with and without NH₃-aging. Based on the Updyke et al. (2012)²³ study and the visual observations of the filter samples, we expect to see evidence of chemical changes

Fig. 4  Distribution of the number of N atoms (top panels) and O atoms (bottom panels) from the identified peaks in the nano-DESI/HR-MS spectra of unreacted (black bars) and NH₃-aged (orange bars) α-pinene SOA (left panels) and limonene SOA (right panels). The picture insets in panel B are the limonene filter samples.

Fig. 5  DBE dependence on the m/z values for all peaks in the nano-DESI-HRMS spectra. Comparison of the unreacted (black) and aged (orange) α-pinene SOA (top) and limonene SOA (bottom). The size of the points is proportional to the normalized peak intensity.
in the NH₃-aged limonene SOA and have focused our analysis on that aerosol. Due to ion fragmentation inherent to the AMS, it is very difficult if at all possible to unambiguously assign molecular formulas to peaks with m/z > 100. The assigned formulae in this analysis are the best estimates based on the information from the nano-DESI/HR-MS data.

It has been shown that ketoaldehydes limononaldehyde (LA) and ketolimononaldehyde (KLA) are abundant and reactive products obtained from the ozonolysis of limonene.⁵⁵ The first-generation products are semi-volatile (exist mainly in the gas phase), while the second-generation products are less volatile and are predominantly found in the aerosol phase. Nguyen et al. (2013)⁶⁴ reported that the unique molecular structure of KLA produces visible-light-absorbing compounds when exposed to ammonia. The KLA-NH₃ reactions produce water-soluble, hydrolysis-resilient chromophores with high mass absorption coefficients, while the first-generation products do not produce light-absorbing compounds following the reaction with ammonia. For this reason we only focus on the KLA products. Fig. 6 shows a mass spectrum normalized to the total organics in the m/z range between 168 to 360 for the unreacted limonene SOA and the aged limonene SOA. The second-generation ozonolysis product of limonene (C₁₀H₁₆O₂), limononaldehyde (LA, C₁₀H₁₆O₂), does not produce light-absorbing compounds following the reaction with ammonia. For this reason we only focus on the KLA products. Fig. 6 shows a mass spectrum normalized to the total organics in the m/z range between 168 to 360 for the unreacted limonene SOA and the aged limonene SOA. The second-generation ozonolysis product of limonene (C₁₀H₁₆O₂), limononaldehyde (KLA, C₁₀H₁₄O₅, m/z 170), can be seen only in the unreacted limonene SOA. The chemistry that produces brown carbon is diverse, with structures of the chromophoric compounds that may be similarly varied in nature, and as mentioned by Nguyen et al. (2013),⁶⁴ it would not be possible to predict the occurrence of these reactions from average properties of aerosols alone, such as the O/C ratio, which is frequently used in correlating physical properties to the average composition. However, Nguyen et al. (2013)⁶⁴ also reported that the KLA-browning reaction generates a diverse mixture of light-absorbing compounds, with the majority of the observable products containing 1–4 units of KLA and 0–2 nitrogen atoms. An example of such a product found after the reaction containing two nitrogen atoms (C₁₉H₁₆O₅N₂) is shown in Fig. 6. The unique reaction products with high DBE detected after the reaction are also shown in Fig. 6. Examples of such products include C₂₀H₂₆O₄N₂ and C₂₁H₂₆O₅N₂ which have a DBE of 10, and C₂₀H₂₆O₄N₂ which has a DBE of 9. These examples show that high DBE values appeared in both the ToF-AMS and nano-DESI/HR-MS measurements only after the reaction with ammonia.

3.5. Comparison of alkene + O₃ SOA without NH₃-aging to literature refractive index values

Recently, there have been an increasing number of studies that retrieved complex refractive indices of SOA generated from monoterpens.⁵³,⁵⁵,⁶⁵,⁶⁶,⁶⁷ They are summarized in Table 1. Among these studies, only a few gave values in the near-UV spectral region (marked in bold in Table 1). For example, for SOA generated from the ozonolysis of α-pinene, Schnaiter et al. (2003)⁵³ reported a constant value of n = 1.44 for λ > 350 nm determined by measuring the wavelength dependence of the SOA scattering and extinction. Using cavity ring down spectroscopy (CRDS), Nakayama et al. (2010)⁵⁷ reported a value of n = 1.458 (±0.019) at λ = 355 nm, and Nakayama et al. (2012)⁵⁹ found values between n = 1.475 (±0.022) and n = 1.463 (±0.019) at λ = 405 nm. Recently, Liu et al. (2013)⁶⁴ using variable angle spectroscopic ellipsometry reported real part values of n = 1.517 (±0.003) and n = 1.509 (±0.003) for λ = 360 nm and λ = 420 nm, respectively. The imaginary components they found in this range were below k < 10⁻⁴. Using a potential aerosol mass (PAM) flow tube reactor to form SOA by homogeneous nucleation and condensation following OH oxidation of α-pinene at different oxidation levels, Lambe et al. (2013)⁶⁷ found RI values between n = 1.51 (±0.02) and n = 1.45 (±0.04) with imaginary part of k < 0.001 at λ = 405 nm, using a CRDS and a photo-acoustic sensor. The values retrieved in our study using BBCES vary from n = 1.48 (±0.03) at λ = 420 nm to n = 1.52 (±0.02) at λ = 360 nm. These values are consistent with the values reported previously and show a small spectral dependence with increasing value of the real part of the refractive index with decreasing wavelength.

For SOA generated from the ozonolysis of limonene, we could only find one recent study that gives the RI in the near UV spectral region. Liu et al. (2013)⁶⁴ measured real parts between 1.520 (±0.003) at λ = 360 nm and 1.512 (±0.003) at λ = 420 nm and imaginary parts below <10⁻⁴. Recently, Flores et al. (2014)⁶⁵ measured the RI of SOA formed by the ozonolysis of a 1:1 mixture of α-pinene and limonene in the SAPHIR chamber in Jülich, Germany, using BBCES. They found values varying from n = 1.511 (±0.011) at λ = 360 nm to 1.485 (±0.010) at λ = 420 nm and no detectable absorption. In the visible range of the spectrum, Kim and Paulson (2013)⁶⁶ measured the RI at λ = 532 nm for the ozonolysis of limonene and found values for the real part of the RI varying from n = 1.4 to 1.5.

For α-humulene we could not find any studies that give the RI in the near UV spectral region to compare with our measurements.

3.6. Atmospheric implications for the measured refractive indices of NH₃-aged biogenic SOA

The organic aerosol aging experiments described here use biogenic VOC concentrations of 10 ppmv and NH₃ concentrations between 0.3 and 1.9 ppmv. Although these mixing ratios are high, relative to ambient values, it has been shown that the chemical composition of limonene SOA formed at high reagent concentrations in a flow tube is similar to that formed with <0.1 ppmv mixing ratios in a smog chamber. Furthermore, Kourchev et al. (2014)89 reported that SOA formed in an atmospheric simulation chamber by the ozonolysis of α-pinene, represents reasonably well the overall composition of ambient samples obtained from a boreal forest. Ammonia represents the primary form of reactive nitrogen in the atmosphere, with emissions of 45–85 Tg N yr⁻¹ estimated in 2008.90 Summertime measurements of ambient NH₃ in southern and central California in 2010 ranged from 10 to 100 ppbv, with values up to 250 ppbv downwind from confined animal dairies.91 Satellite measurements of NH₃ in 2008 identify 26 additional global hotspots with annually-averaged columns greater than 0.5 mg m⁻² (equivalent to 0.7 ppbv for a 1000 m planetary boundary layer).92 If we assume that the NH₃ aging reactions may scale linearly with time and concentration (an assumption that needs verification), then 1.5 h reaction with 1 ppm NH₃ would be equivalent to 24 h reaction with 63 ppbv NH₃, indicating that the laboratory measurements explore the full range of atmospherically-relevant NH₃ gas-phase concentrations.

Table 2 summarizes MAC and k values from different field and laboratory studies reported in the literature. The absorption values measured here for NH₃-aged aerosol are similar in magnitude to these values. Besides the Lack et al. (2012) study, our values fall at the lower end of the absorption in the near ultraviolet spectral region. These differences might come from the fact that we do not know what parts of the ambient measurements are aged biogenic SOA and which are primary pollution or mineral dust. Here we considered only biogenic SOA generated from the reaction of biogenic alkenes with O₃ and its subsequent browning by NH₃. The low k values (k < 0.01 for all NH₃ concentrations less than 1 ppm) are generally
consistent with the small MAC and $k$ values observed for brown carbon in the atmosphere.

To test the impact from the greatest change in the imaginary part of the retrieved RI values on aerosol optical properties and radiative forcing at the Earth’s surface, we use the “simple forcing efficiency” proposed by Bond and Bergstrom (2006). The calculation of the SFE is a simple calculation to determine atmospheric importance, while a full radiative transfer model is needed to accurately determine forcing efficiency. For these calculations, we assume an average earth surface albedo of 0.19, a density of $\rho = 1.4$ g cm$^{-3}$, and a median aerosol diameter of 150 nm for the Mie calculations. Two SFE calculations were done, for each calculation we assume a constant n value of 1.50, and for the values of $k$ we used $k = 0.0$ and $k = 0.05$ (the upper bound from the average change in $k$ observed in the $\alpha$-humulene and limonene SOA). These assumptions were made to obtain the maximal change in the forcing efficiency, since the $k$ value ought to be wavelength dependent over the 360–910 nm range.

Fig. 7 shows the SFE for the two cases for wavelengths between 360 and 910 nm. The integrated forcing for the $m = 1.5 + 0.0i$ case (black line) is $-28$ W g$^{-1}$, and for the $m = 1.5 + 0.05i$ case is $-9.6$ W g$^{-1}$. These observed changes in the refractive index due to aging by NH$_3$ indicate that the cooling effect by the aerosol can decrease by a factor of three. This drastic change may only occur where NH$_3$ concentrations reach levels $>$1 ppm, as has been observed in forest fire plumes, or where aerosol is exposed to more moderate levels of NH$_3$ ($\sim$60 ppbv) for 24 h.

4. Summary and conclusions

We measured the change in the complex refractive index in the 360–420 nm wavelength range for SOA formed by the ozonolysis of $\alpha$-pinene, limonene, and $\alpha$-humulene (three biogenic VOC precursors), when exposed to different concentrations of NH$_3$. For the $\alpha$-pinene SOA there was a change in the real part of the RI from an average $n = 1.50 \pm 0.01$ for the unreacted SOA to $n = 1.57 \pm 0.01$ after a 1.5 h exposure to 1.9 ppm NH$_3$. For limonene SOA and $\alpha$-humulene SOA, we observed a small change in the imaginary component of the RI. The imaginary component increased to an average $k = 0.029 \pm 0.021$ for $\alpha$-humulene SOA, and to an average $k = 0.032 \pm 0.019$ for limonene SOA after a 1.5 h exposure to 1.3 and 1.9 ppm of NH$_3$, respectively. Collected filter samples of aged and unreacted $\alpha$-pinene SOA and limonene SOA were analyzed by nano-DESI/HR-MS, and in situ using a ToF-AMS, confirming that the chemical reaction occurred and that N-containing reaction products were formed. The NH$_3$-aged limonene SOA filter changed to light orange in color, indicating the formation of light-absorbing products. The nano-DESI/HR-MS analysis showed that the number of N-containing molecules increases significantly from the unreacted samples. Furthermore, there are indications that high double bond equivalent values are needed for the formation of brown carbon. The ToF-AMS analysis showed products which appear only after the reaction with NH$_3$, and were also shown to have high DBE values. If we assume that NH$_3$ aging reactions scale linearly with time and concentration, then a 1.5 h reaction with 1 ppm NH$_3$ in the laboratory is equivalent to 24 h reaction with 63 ppbv NH$_3$, indicating that the observed aerosol absorption will be limited to atmospheric regions with high NH$_3$ concentrations.

To assess the sensitivity of the BBCES RI retrievals, we measured atomized samples of a humic-like substance proxy, Suwannee River fulvic acid, and a filter extract of NH$_3$-aged limonene SOA
generated at UC-Irvine, which was light orange in color. We found $k$ values of the order of 0.05 for SRFA and no detectable absorption for the NH$_3$-aged limonene SOA in the 360–420 nm range. UV/Vis absorption spectra were used to determine mass absorption coefficients and $k$ values for SRFA, NH$_3$-aged limonene SOA generated at UC Irvine, and NH$_3$-aged limonene SOA generated in this study. SRFA showed approximately an order of magnitude greater absorption than the two NH$_3$-aged limonene SOA samples. We calculated the MAC for the filter samples to be <0.2 m$^2$ g$^{-1}$, which corresponds to imaginary parts of 0.008–0.009 for wavelengths between 360 and 420 nm and $\rho = 1.4$ g cm$^{-3}$. With such small MAC and $k$ values, the BrC formed by the interaction of biogenic SOA with ammonia is expected to make a significant contribution to the absorption in the atmosphere only where ammonia concentrations are greater than 1 ppm for 1.5 h or where NH$_3$ exposure times are proportionally longer (e.g. 63 ppbv for 24 h). In these cases, the simple forcing efficiency calculation showed that the cooling effect by the aerosol can be decreased by up to a factor of three.

The use of SRFA as a proxy for a humic-like substance proved useful to verify that there were no errors with the instrumental method or the refractive index retrieval, but it also showed that its optical properties, specifically its absorption properties, are significantly higher than those of the NH$_3$-aged SOA and other BrC measured in the field. Therefore, the use of SRFA as a BrC standard should be taken with caution as the absorption can be significantly overestimated.

The in situ measurements of aerosol extinction and retrieved complex refractive indices from this study demonstrate that bulk phase experiments of brown carbon can sensitively and reliably identify chemical shifts that lead to absorbing components. However, the in situ measurements of aerosol optical properties at relevant atmospheric size distributions provide an essential confirmation of the real atmospheric impact of such absorption, and should be included together with bulk phase experiments when possible. The absorption observed in bulk phase experiments suggests that a variety of potential organic chromophores may give rise to BrC components. However, quantitative assessment of their impact on climate requires in situ aerosol optical measurements, such as refractive index retrievals, over a broad spectral range.
