Peer reviewed
The shoulder joint is a complex array of muscles, tendons, and capsuloligamentous structures that has the greatest freedom of motion of any joint in the body. Acute (<2 weeks) shoulder pain can be attributable to structures related to the glenohumeral articulation and joint capsule, rotator cuff, acromioclavicular joint, and scapula. The foundation for investigation of acute shoulder pain is radiography. Magnetic resonance imaging is the procedure of choice for the evaluation of occult fractures and the shoulder soft tissues. Ultrasound, with appropriate local expertise, is an excellent evaluation of the rotator cuff, long head of the biceps tendon, and interventional procedures. Fluoroscopy is an excellent modality to guide interventional procedures. Computed tomography is an excellent modality for characterizing complex shoulder fractures. Computed tomographic arthrography or fluoroscopic arthrography may be alternatives in patients for whom MR arthrography is contraindicated. A multimodal approach may be required to accurately assess shoulder pathology. The ACR Appropriateness Criteria® are evidence-based guidelines for specific clinical conditions that are reviewed every 2 years by a multidisciplinary expert panel. The guideline development and review include an extensive analysis of current medical literature from peer-reviewed journals and the application of a well-established consensus methodology (modified Delphi) to rate the appropriateness of imaging and treatment procedures by the panel. In those instances in which evidence is lacking or not definitive, expert opinion may be used to recommend imaging or treatment.

Key Words: Appropriateness Criteria®, acute shoulder pain, labral tear, shoulder arthroplasty, septic arthritis, rotator cuff repair

SUMMARY OF LITERATURE REVIEW

Introduction
The shoulder has the greatest freedom of motion of any joint in the body. The shoulder joint is a complex array of muscles, tendons, and capsuloligamentous structures that demonstrate a wide variety of pathology. Acute (<2 weeks) shoulder pain can be attributable to structures related to the glenohumeral articulation and joint capsule, rotator cuff, acromioclavicular joint, and scapula. Radiography is a safe, fast, low-cost imaging modality that effectively demonstrates many forms of shoulder pathology. However, a multimodal approach may be required to accurately assess shoulder pathology.

Radiography
Radiography is a useful initial screening modality for acute shoulder pain of all causes (see Variant 1). Radiography is useful in the evaluation of fractures of the shoulder girdle. All radiographic shoulder studies should include frontal examinations. The frontal views can be straight anteroposterior (AP) projections with the humerus in the neutral position or with the humerus in internal or without external rotation. Local protocols for radiographic evaluation of the shoulder for trauma vary widely. However, the shoulder trauma protocol should have ≥3 views, of which 2 are orthogonal. For trauma, a Grashey projection is recommended to profile the glenohumeral joint, which is AP to the scapula, by turning the patient into a 30° posterior oblique profile [1]. For trauma, this examination should have an axillary lateral view, a scapular Y view, or both [1-4]. The axillary lateral view or scapular Y view is advisable if there is a question of instability or dislocation [1,5]. However, the position required for the axillary lateral view may be painful for patients who have just dislocated their shoulders. Care should be taken if the shoulder has just been reduced because this positioning may lead to redislocation.

The transthoracic view has little to offer but is not infrequent when outside radiographs become available for review. There have been several reports assessing special views for the evaluation of shoulder impingement and the anterior acromion [3,4,6]. An upright 30° angled caudad radiograph (Rockwood view) or a suprascapular outlet view will suffice in most cases [6,7]. A radiograph taken with the patient prone with the shoulder resting on a cushion and arm abducted 90°, with the forearm and hand in pronation, hanging downward off the edge of the table (Westpoint view), can improve detection of a bony Bankart lesion [1]. A radiograph taken with patient in the supine position with the arm externally rotated and abducted and the x-ray beam angled 10° cephalad and centered on the coracoid process (Stryker notch view) used with an AP internal rotation view, is a sensitive technique for the evaluation of a Hill-Sachs deformity [1].

Fluoroscopic arthrography was the mainstay of evaluation for rotator cuff tear until the advent of shoulder MRI. Fluoroscopic arthrography is currently used only as a potential study in patients with suspected rotator cuff disease who have contraindications to MRI and when shoulder ultrasound expertise is not available (see Variant 7). Fluoroscopic radiography is a useful modality for directing shoulder injections and aspirations (see Variant 8). Aspirations are useful in differentiating between inflammatory and septic arthropathy. Fluoroscopic arthrography can be a useful tool in experienced hands.

**Variant 3.** Radiographs noncontributory; age < 35 years, suspect labral tear with or without instability on physical examination

MRI

MRI can aid in detecting osseous and soft tissue abnormalities that may predispose to or be the result of shoulder impingement [8,9]. The soft tissue abnormalities in the supraspinatus tendon, subacromial bursa, and biceps tendon are well seen [10]. The osseous lesions include morphologic abnormalities of the acromion and acromioclavicular joint. When a tendon has a signal intensity abnormality without focal disruption or associated findings to suggest a partial-thickness tear, the terms tendinosis and tendinopathy have been used to signify an underlying tendon degeneration or inflammation. These terms suggest that there is a chronic degenerative process. The presence of tendinous enlargement and a heterogeneous signal pattern that demonstrates diffuse increased signal intensity on T1 weighting, often with a slight increase in signal intensity on T2 weighting, is seen in patients with tendinosis. Partial-thickness tears of the rotator cuff can be seen inferiorly at the articular surface, superiorly at the bursal surface or within the tendon substance. Tears at the articular surface are the most common type of partial-thickness tears. These are the only types of partial-thickness tears demonstrated by conventional shoulder arthrography [11]. Full-thickness tears of the rotator cuff tendon can be accurately identified using conventional nonarthrographic MRI, with high sensitivity and specificity. Increased signal intensity extending from the inferior to the superior surface of the tendon on all imaging sequences is an accurate sign of a full-thickness rotator cuff tear [8]. Ten percent of rotator cuff tears are asymptomatic and present only with morphologic changes. Tendon retraction, muscle atrophy, and fatty infiltration are important findings that can be useful for decisions regarding conservative versus operative repair, type of operative repair (open, mini-open, or arthroscopic cuff repair; substitute; or muscle transfer) and to provide a postoperative prognosis. If there is any question concerning the distinction between a full-thickness and partial-thickness tear, MR arthrography (MRA) is recommended. It is particularly helpful if the abnormal signal intensity extends from the undersurface of the tendon.
The shoulder joint is the most unstable joint in the body. Instability can be difficult to diagnose, and the pain produced by the unstable shoulder could be mistaken for that of shoulder impingement, cervical disk disease, acromioclavicular joint disease, and other processes. During the past decade, MRI has allowed the direct visualization of many of the lesions related to instability, aiding in diagnosis as well as therapeutic planning and follow-up (see Variant 2). Although high-resolution nonenhanced MRI has been shown to have high accuracy rates for demonstrating labral tears, direct MRA with intra-articular injection of a dilute gadolinium solution has gained popularity during the past decade because of its ability to distend the joint and outline labral and capsular structures as well as the undersurface of the rotator cuff [9,11-20]. Currently, MRA is generally recommended for patients aged < 35 years, because instability has been shown to be predominately related to rotator cuff disease in older patients [21,22] (see Variant 3). Magnetic resonance imaging can also play an important role in imaging the postoperative shoulder and in the evaluation of shoulder hardware [23,24] (see Variants 6 and 7).

CT
CT is useful for characterizing fractures, if more information is needed preoperatively. It can demonstrate fracture complexity, displacement, and angulation, especially with the use of reconstructed images [25,26]. Multidetector CT can produce high-quality isotropic imaging. This can be helpful in evaluating a shoulder with metallic hardware. The evaluation of a metallic prosthesis can be optimized by using a higher voltage (140 kVp), higher exposure (200–400 mAs), and reduced pitch with slice overlap (<1). This will improve image quality but also result in increased radiation dose [27]. This panel’s consensus opinion is that CT shoulder arthrography is superior to MRI or MRA in the evaluation of the rotator cuff in the setting of a previous shoulder arthroplasty (see Variant 6). Computed tomographic arthrography is useful for the evaluation of the postoperative labrum, rotator cuff, and loosening around implants (see Variants 3, 6, and 7). Computed tomographic arthrography is a second-line procedure for shoulders with suspected instability or labral disorders, when MRA and MRI are unavailable or contraindicated [28] (see Variant 3).

Ultrasound
Ultrasound can be used to evaluate the acromioclavicular joint, the tendons of the rotator cuff, and the long head of biceps tendon. It is operator dependent and limited in evaluation of the other important deep shoulder structures and marrow. Ultrasound-guided injections and aspirations are helpful in treating and diagnosing shoulder pain, with appropriate local expertise (see Variants 7 and 8).

Ultrasound can be used to determine if a partial-thickness or full-thickness rotator cuff tear is present [29]. Ultrasound is equivalent to MRI, with appropriate local expertise, in the evaluation of rotator cuff tears [7]. Ultrasound can also play an important role in the evaluation of the postoperative shoulder and in rotator cuff integrity after shoulder replacement [30] (see Variants 2, 4, and 5-7).

Neoplasm
Neoplasm is another cause of shoulder pain, and (diagnostically) these lesions can be approached like other neoplasms in the musculoskeletal system (see the ACR Appropriateness Criteria® on soft tissue masses and the ACR Appropriateness Criteria on primary bone tumors).
Osteomyelitis can be a cause of shoulder pain, although there are no current recommendations by this committee other than for osteomyelitis of the foot (see the ACR Appropriateness Criteria on suspected osteomyelitis of the foot in patients with diabetes mellitus).

SUMMARY

The mainstay in initial imaging of shoulder trauma is radiography. Radiography provides a quick, inexpensive evaluation for fracture and dislocation.

A good shoulder trauma radiography protocol includes AP, Grashey, axillary, and/or scapular Y projections. Special projections include the Rockwood view for evaluation of shoulder impingement, the Westpoint view for Bankart fractures, and the Stryker notch view for Hill-Sachs fractures.

MRI is currently the procedure of choice for the evaluation of occult fractures and the shoulder soft tissues, including the tendons, ligaments, muscles, and labrocapsular structures. The shoulder MRI protocol may or may not include gadolinium, depending on the clinical question. MRI and MRA are the modalities of choice in evaluation of patients aged <35 years with shoulder pain and in patients with instability and/or questionable labral pathology.

Ultrasound with appropriate local expertise is excellent in the depiction of rotator cuff and long head of biceps pathology in the preoperative and postoperative shoulder. It is an excellent modality to guide injections and aspirations.

Fluoroscopic arthrography was the mainstay of evaluation for rotator cuff tear until the advent of shoulder MRI. It is an excellent modality to guide injections and aspirations. Fluoroscopic arthrography is currently used only as a potential study in patients with suspected rotator cuff disease who have contraindications to MRI and when shoulder ultrasound expertise is not available.

CT without contrast is useful for characterizing fractures, if more information is needed preoperatively. It can demonstrate fracture complexity, displacement, and angulation, especially with the use of reconstructed images. This panel’s consensus opinion is that CT shoulder arthrography is superior to MRI or MRA in the evaluation of the rotator cuff in the setting of a previous shoulder arthroplasty. CT arthrography is useful for evaluation of the cuff and loosening around implants. CT arthrography is a good alternative in patients who have a contraindication to MRI or MRA.

ANTICIPATED EXCEPTIONS

Nephrogenic systemic fibrosis is a disorder with a scleroderma-like presentation and a spectrum of manifestations that can range from limited clinical sequelae to fatality. It seems to be related to both underlying severe renal dysfunction and the administration of gadolinium-based contrast agents. It has occurred primarily in patients on dialysis, rarely in patients with very limited glomerular filtration rates (ie, <30 mL/min/1.73 m²), and almost never in other patients. There is growing literature regarding nephrogenic systemic fibrosis. Although some controversy and lack of clarity remain, there is a consensus that it is advisable to avoid all gadolinium-based contrast agents in dialysis-dependent pa-
patients unless the possible benefits clearly outweigh the risk and to limit the type and amount in patients with estimated glomerular filtration rates \(< 30 \text{ mL/min/1.73 m}^2\). For more information, please see the ACR’s Manual on Contrast Media [31].

### RELATIVE RADIATION LEVEL INFORMATION

Potential adverse health effects associated with radiation exposure are an important factor to consider when selecting the appropriate imaging procedure. Because there is a wide range of radiation exposures associated with different diagnostic procedures, an relative radiation level indication has been included for each imaging examination. The relative radiation levels are based on effective dose, which is a radiation dose quantity that is used to estimate population total radiation risk associated with an imaging procedure. Patients in the pediatric age group are at inherently higher risk from exposure, both because of organ sensitivity and longer life expectancy (relevant to the long latency that appears to accompany radiation exposure). For these reasons, the relative radiation level dose estimate ranges for pediatric examinations are lower compared with those specified for adults (Table 1). Additional information regarding radiation dose assessment for imaging examinations can be found in ACR Appropriateness Criteria: Radiation Dose Assessment Introduction [32].

For additional information on ACR Appropriateness Criteria, refer to http://www.acr.org/ac.
