We report the results of a Dark Energy Camera optical follow-up of the gravitational-wave (GW) event GW151226, discovered by the Advanced Laser Interferometer Gravitational-wave Observatory (LIGO) detectors. Our observations cover 28.8 deg$^2$ of the localization region in the $i$ and $z$ bands (containing 3% of the BAYESTAR localization probability), starting 10 hr after the event was announced and spanning four epochs at 2–24 days after the GW detection. We achieve 5$\sigma$ point-source limiting magnitudes of $i \approx 21.7$ and $z \approx 21.5$, with a scatter of 0.4 mag, in our difference images. Given the two-day delay, we search this area for a rapidly declining optical counterpart with $\gtrsim 3\sigma$ significance steady decline between the first and final observations. We recover four sources that pass our selection criteria, of which three are cataloged active galactic nuclei. The fourth source is offset by $\approx 75$ Mpc, a 40-fold increase in volume relative to the previous generation of ground-based gravitational-wave (GW) detectors (The LIGO Scientific Collaboration et al. 2016). On 2015 September 14, LIGO detected the first GW event ever observed, GW150914 (Abbott et al. 2016a).

The waveform of GW150914 was consistent with the inspiral, merger, and ring-down of a binary black hole (BBH) system ($\approx 75$ Mpc, a 40-fold increase in volume relative to the previous generation of ground-based gravitational-wave (GW) detectors (The LIGO Scientific Collaboration et al. 2016). On 2015 September 14, LIGO detected the first GW event ever observed, GW150914 (Abbott et al. 2016a).

The Advanced Laser Interferometer Gravitational-wave Observatory (LIGO) is designed to detect the final inspiral and merger of compact object binaries comprised of neutron stars (NSs) and/or stellar-mass black holes (BHs; Abbott et al. 2009). The first LIGO observing run (designated O1) commenced on 2015 September 18 with the ability to detect binary neutron star (BNS) mergers to an average distance of $\approx 75$ Mpc, a 40-fold increase in volume relative to the previous generation of ground-based gravitational-wave (GW) detectors (The LIGO Scientific Collaboration et al. 2016). On 2015 September 14, LIGO detected the first GW event ever observed, GW150914 (Abbott et al. 2016a).

The waveform of GW150914 was consistent with the inspiral, merger, and ring-down of a binary black hole (BBH) system ($36 + 29 M_\odot$; Abbott et al. 2016a) providing the first observational evidence that such systems exist and merge. While there are no robust theoretical predictions for the expected electromagnetic (EM) counterparts of such a merger, more than 20 teams conducted a wide range of follow-up observations spanning from radio to $\gamma$-rays, along with neutrino follow-up (Abbott et al. 2016b; Adrian-Martinez et al. 2016; Annis et al. 2016; Connaughton et al. 2016; Evans et al. 2016; Kasliwal et al. 2016; Savchenko et al. 2016; Smartt et al. 2016; Soares-Santos et al. 2016; Tavani et al. 2016). This effort included deep optical follow-up observations by our group using Dark Energy Camera (DECam) covering 100 deg$^2$ (corresponding to a contained probability of 38% (11%) of the initial (final) sky maps)—making this one of the most comprehensive optical follow-up campaigns for GW150914 (Annis et al. 2016; Soares-Santos et al. 2016). Our search for rapidly declining transients to limiting magnitudes of $i \approx 21.5$ mag for red ($i - z = 1$) and $i \approx 20.1$ mag for blue ($i - z = -1$) events yielded no counterpart to GW150914 (Soares-Santos et al. 2016). One result of the broader multi-wavelength follow-up campaign is a claimed coincident detection of a weak short gamma-ray burst (SGBRB) from the Fermi-GBM detector 0.4 s after the GW event (Connaughton et al. 2016). However, this event was not detected in INTEGRAL $\gamma$-ray data (Savchenko et al. 2016) and was also disputed in a re-analysis of the GBM data (Greiner et al. 2016).

A second high-significance GW event, designated GW151226, was discovered by LIGO on 2015 December 26 at 03:38:53 UT (Abbott et al. 2016c). This event was also due to the inspiral and merger of a BBH system, consisting of $14.2^{+8.3}_{-3.7}$ $M_\odot$ and $7.5^{+2.3}_{-1.0}$ $M_\odot$ BHs at a luminosity distance of $d_L = 440^{+180}_{-190}$ Mpc (Abbott et al. 2016c). The initial localization was provided as a probability sky map via a private GCN circular 38 hr after the GW detection (LIGO Scientific Collaboration & Virgo 2015). We initiated optical follow-up observations with DECam 10 hr later on 2015 December 28 and imaged a 28.8 deg$^2$ region in the $i$ and $z$ bands during several epochs. Here, we report the results of this search. In Section 2, we discuss the observations and data analysis procedures. In Section 3, we present our search methodology for potential counterparts to GW151226 and the results of this search. We summarize our conclusions in Section 4. We perform cosmological calculations assuming $H_0 = 67.8$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_\Lambda = 0.69$, and $\Omega_m = 0.31$ (Planck Collaboration et al. 2015). Magnitudes are reported in the AB system.
2. OBSERVATIONS AND DATA REDUCTION

GW151226 was detected on 2015 December 26 at 03:38:53 UT by a Compact Binary Coalescence (CBC) search pipeline Abbott et al. (2016e). The CBC pipeline operates by matching the strain data against waveform templates and is sensitive to mergers containing NSs and/or BHs. The initial sky map was generated by the BAYESTAR algorithm and released 38 hr after the GW detection. BAYESTAR is a Bayesian algorithm that generates a localization sky map based on the parameter estimation from the CBC pipeline (Singer et al. 2014; Singer & Price 2016). The sky area contained within the initial 50% and 90% contours was $\approx 430$ deg$^2$ and 1340 deg$^2$, respectively. A sky map generated by the LALInference algorithm, which computes the localization using Bayesian forward-modeling of the signal morphology (Veitch et al. 2015), was released on 2016 January 15 UT, after our DECam observations had been concluded. The LALInference sky map is slightly narrower than the sky map from BAYESTAR with 50% and 90% contours of 362 deg$^2$ and 1238 deg$^2$, respectively.

We initiated follow-up observations with DECam on 2015 December 28 UT, two days after the GW detection and 10 hours after distribution of the BAYESTAR sky map. DECam is a wide-field optical imager with a 3 deg$^2$ field of view (Flaugher et al. 2015). We imaged a 28.8 deg$^2$ region corresponding to 3% of the sky localization probability when convolved with the initial BAYESTAR map and 2% of the localization probability in the final LALInference sky map. The pointings and ordering of the DECam observations were determined using the automated algorithm described in Soares-Santos et al. (2016). The choice of observing fields was constrained by weather, instrument availability, and the available time to observe this sky region given its high airmass. We obtained four epochs of data with each epoch consisting of one 90 s exposure in the $i$-band and two 90 s exposures in the $z$-band for each of the 12 pointings. The first epoch was obtained 2–3 days after the GW event time (2015 December 28–29 UT), the second epoch was at 6 days (2016 January 1 UT), the third epoch was at 13–14 days (2016 January 8–9), and the fourth epoch was at 23–24 days (2016 January 18–19). A summary of the observations is provided in Table 1, and a visual representation of the sky region is shown in Figure 1.

We processed the data using an implementation of the photpipe pipeline modified for DECam images. Photpipe is a pipeline used in several time-domain surveys (e.g., SuperMACHO, ESSENCE, Pan-STARRS1; see Rest et al. 2005; Garg et al. 2007; Miknaitis et al. 2007; Rest et al. 2014), designed to perform single-epoch image processing including image calibration (e.g., bias subtraction, cross-talk corrections, flat fielding), astrometric calibration, image coaddition, and photometric calibration. Additionally, photpipe performs difference imaging using hotpants (Alard 2000; Becker 2015) to compute a spatially varying convolution kernel, followed by photometry on the difference images using an implementation of DoPhot optimized for point-spread function (PSF) photometry on difference images (Schechter et al. 2016).

Notes. Summary of our DECam follow-up observations of GW151226. The PSF, airmass, and depth are the average values across all observations on that date. The reported depth corresponds to the mean 5$\sigma$ point-source detection in the coadded search images.

$^a$ Time elapsed between the GW trigger time and the time of the first image.

$^b$ The effective area corresponds to 12 DECam pointings taking into account that $\approx$20% of the 3 deg$^2$ field of view of DECam is lost due to chip gaps (10%), three dead CCDs (5%; Diehl et al. 2014), and masked edge pixels (5%).
that re-brighten in the fourth (template) epoch. This provides an initial sample of 602 candidates.

2. We require $\geq 5\sigma$ $i$- and $z$-band detections in the first epoch and at least one additional $\geq 5\sigma$ $i$-band detection in either of the two remaining epochs (to eliminate contamination from astroids). This criterion leaves a sample of 98 objects.

3. We require a $\geq 3\sigma$ decline in flux between the first and third epochs to search for significant fading.\textsuperscript{61} We calculate $\sigma$ as the quadrature sum of the flux errors from the first and third epochs ($\sigma = \sqrt{\sigma_1^2 + \sigma_2^2}$, where $\sigma_1$ and $\sigma_2$ are the flux errors from the first and third epochs, respectively). This criterion leaves a sample of 48 objects.

4. We reject sources that exhibit a significant ($\geq 3\sigma$) rise in flux between the first and second epochs or the second and third epochs to eliminates variable sources that do not decline steadily. This criterion leaves a sample of 32 objects.

5. The remaining 32 candidates from step 4 undergo visual inspection. We reject sources that are present as a point source in the fourth (template) epoch that do not have a galaxy within 20″. Sources are cross-checked against NED\textsuperscript{62} and SIMBAD.\textsuperscript{63} This criterion is designed to remove variable stars and long-timescale transients.

Only four events passed our final criterion. We find that two of those events are coincident with the nuclei of known active galactic nuclei (AGNs; PKS 0129-066 and Mrk 584), indicating that they represent AGN variability. A third candidate is coincident with the nucleus of the bright radio source PMN J0203+0956 ($F_\nu (365\text{ MHz}) \approx 0.4\text{ Jy}$; Douglas et al. 1996), also suggesting AGN variability.

The final candidate in our search is located at R.A. = 01^h42^m16.1^s and decl. = −02°13′42.6″ (J2000), with an offset of 5.8 arcsec from the galaxy CGCG 386-030 (R.A. = 01^h42^m15.7^s, decl. = −02°13′38.5″; J2000), at $z = 0.041$ or $d_L \approx 178\text{ Mpc}$ (6dFGS; Jones et al. 2004, 2009; see Figure 2). We note that this distance is inconsistent with the 90% confidence interval for the distance to GW151226 based on the GW data (Abbott et al. 2016c). We observe this source in a state of rapid decline with an absolute magnitude of $M_i \approx −15\text{ mag}$ on 2015 December 28 and $M_i \approx −14.5\text{ mag}$ on 2016 January 1, indicating a decline rate of $≈0.12\text{ mag d}^{-1}$; the decline rate in the $z$-band is $≈0.10\text{ mag d}^{-1}$. Additionally, the source exhibits a red $i−z$ color of 0.3 mag. We fit these data to a power-law model typical for GRB afterglows ($F_\nu \propto \nu^{\beta}$) and find a temporal index of $α = −0.43 \pm 0.12$ and a spectral index of $β = −1.8 \pm 0.8$, both of which differ from the expected values for GRB afterglows ($α \approx −1$, $β \approx −0.75$; Sari et al. 1998). Additionally, we compare our observations to a kilonova model with ejecta parameters of $v_\infty = 0.2c$ and $M_{ej} = 0.1 M_\odot$ (Barnes & Kasen 2013). We find that the timescale of the transient agrees with those expected for kilonovae, but the color is bluer than the expected value of $i−z \approx 1\text{ mag}$ (Barnes & Kasen 2013).

\textsuperscript{61} We note that this criterion effectively requires the detection in the first epoch to be $\geq 5\sigma$, producing an effectively shallower transient search. Soares-Santos et al. (2016) quantified this effect by injecting fake sources into their observations to determine the recovery efficiency and loss of detection depth from analysis cuts. Here, we forego such analysis to focus the discussion on the effects of contamination in optical follow-up of GW events.

\textsuperscript{62} https://ned.ipac.caltech.edu/

\textsuperscript{63} http://simbad.u-strasbg.fr/simbad/
Thus, the properties of this transient differ from those of GRB afterglows or kilonovae. The observations and models are shown in Figure 2.

This source was previously detected as PS15cdi on 2015 September 23 by the Pan-STARRS Survey for Transients (PSST64; Huber et al. 2015; see Figure 2). The absolute i-band magnitude in the first PSST epoch, $M_i \approx -16.6$ mag, and the shallow decline of $\approx 0.6$ mag over $\approx 70$ d are consistent with a Type IIP core-collapse supernova (SN). A likely interpretation of the rapid decline in our observations is that PS15cdi is a Type IIP SN undergoing the rapid transition from the hydrogen recombination driven plateau to the radioactive $^{56}$Co-dominated phase (Kasen & Woosley 2009; Sanders et al. 2015; Dhungana et al. 2016). The red $i - z$ color in our data is consistent with observations of other IIP SN during this phase of evolution (e.g., SN2013ej; Dhungana et al. 2016). This transition typically occurs about 100 days post-explosion (Kasen & Woosley 2009; Sanders et al. 2015; Dhungana et al. 2016), consistent with the timing of our observations relative to the first detection in PSST.

To mitigate the effect of excess flux from PS15cdi still present in our template observations, we repeat the analysis using as templates archival DES i- and z-band images from 2013 December 19. These data were processed and image subtraction was performed as described in Section 2. We find that flux from PS15cdi is indeed still present in our original template image, leading to revised first epoch absolute magnitudes of $M_i \approx -15.6$ and $M_z \approx -16$ mag, and a decline rate between the first and fourth epochs of 0.04 mag d$^{-1}$, in

---

Figure 2. Top: single-epoch images of our main candidate from all four epochs (green circle). This is the event discovered as PS15cdi in the PSST about 94 days prior to GW151226. Bottom: light curve data for PS15cdi from PSST u- and i-band observations (green squares and yellow diamonds, respectively). Our DECam i- and z-band data are shown as blue circles and red stars, respectively. The revised DECam analysis using pre-existing templates is shown as open symbols. Upper limits are indicated by triangles. The inset focuses on our DECam data, indicating a rapid decline in both the i and z bands. We fit a power-law model to the data finding a temporal index of $\alpha = -0.43$ (dashed-dotted line). Kilonova models from Barnes & Kasen (2013) with $v_0 = 0.2c$ and $M_0 = 0.1M_\odot$ at a distance of 187 Mpc are also shown (dashed line).
both the $i$ and $z$ bands. The transient still exhibits a red $i - z$ colors of $\approx 0.4$ mag across all four epochs.

Clearly, we can rule out this candidate based on the PSST detections prior to GW151226, but without this crucial information this candidate would have been a credible optical counterpart based on its light curve behavior and distance. It is therefore useful to develop an understanding of the expected rates for such contaminants to inform expectations in future searches. We adopt a local core-collapse SN rate of $7 \times 10^{-3} \text{yr}^{-1} \text{Mpc}^{-3}$ (Li et al. 2011; Cappellaro et al. 2015) and a Type IIP SN fraction of 48% of this rate (Smith et al. 2011). The rapid decline phase typically lasts about 20 days (Kasen & Woosley 2009; Sanders et al. 2015; Dhungana et al. 2016), so we consider events that occur within that time frame. Last, given its apparent brightness, we assume that PS15cdi represents the approximate maximum distance to which we can observe these events in our data. We thus find an expected occurrence rate of $\sim 0.04$ events in our search area making our detection of PS15cdi somewhat unlikely and indicating that $\lesssim 1$ such events are expected in a typical GW localization region.

Our detection of PS15cdi clearly demonstrates the presence and impact of contaminants when conducting optical follow-up of GW events. Core-collapse SNe are generally not considered to be a significant contaminant due to their much longer timescales compared to kilonovae (e.g., Cowperthwaite & Berger 2015). However, a source like PS15cdi, caught in a rapid phase of its evolution despite its overall long timescale and exhibiting a relatively red color, could satisfy a set of criteria designed for finding kilonovae ($\Delta m \geq 0.1$ mag d$^{-1}$ and $i - z \gtrsim 0.3$ mag; Cowperthwaite & Berger 2015).

The most effective approach to dealing with contaminants like PS15cdi is rapid, real-time identification. Once a candidate is deemed interesting, optical spectroscopy and NIR photometry can quickly distinguish between an SN or a kilonova/afterglow origin. Specifically, the kilonova spectrum will be redder, with clear suppression below $\sim 6000 \text{Å}$ due to the opacities of $r$-process elements (Kasen et al. 2013). By comparison, the SN spectrum will appear bluer and dominated by iron group opacities (Kasen et al. 2013), while the afterglow spectrum will exhibit a featureless power-law spectrum (Berger 2014). If pre-existing templates are not available, then the significant aspect is rapid initiation of follow-up observations at $\lesssim 1$ day that can distinguish the rising phase of a kilonova or off-axis GRB from a declining SN.

4. CONCLUSIONS

We presented the results of our deep optical follow-up of GW151226 using the DECam wide-field imager. Our observations cover a sky area of 28.8 deg$^2$, corresponding to 3% of the initial BAYESTAR probability map and 2% of the final LALInference map. We obtained four epochs of observations starting 10 hr after the event was announced and spanning 2-24 days post-trigger, with an average $5\sigma$ point-source sensitivity of $i \approx 21.7$ and $z \approx 21.5$, with an epoch-to-epoch scatter of 0.4 mag, in our difference images.

Using the final epoch as a template image, we searched for sources that display a significant and steady decline in brightness throughout our observations and that are not present in the template epoch. This search yielded four transients, of which three result from AGN variability. The final event is located at a distance of about 187 Mpc offset by 5".8 from its host galaxy. It also broadly possesses the observational features of a kilonova in terms of its rapid decline and red $i - z$ color. However, this source corresponds to the transient PS15cdi, which was discovered in PSST about 94 days prior to the GW trigger. It is a likely Type IIP SN, which our observations caught in the steep transition at the end of the plateau phase. The detection of this event indicates that careful rejection of contaminants, preferably in real time, is essential in order to avoid misidentifications of optical counterparts to GW sources.

NOAO is operated by the Association of Universities for Research in Astronomy (AURA), Inc. under a cooperative agreement with the National Science Foundation. The computations in this Letter were run on the Odyssey cluster supported by the FAS Division of Science, Research Computing Group at Harvard University. This research has made use of the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. Light curve data for PS15cdi were obtained from The Open Supernova Catalog (Guillochon et al. 2016). Some of the results in this Letter have been derived using the HEALPix package (Górski et al. 2005).

Funding for the DES Projects has been provided by the DOE and NSF (USA), MEC/MICINN/MINECO (Spain), STFC (UK), HIFEC (UK), NCSA (UIUC), KICP (U. Chicago), CCAPP (Ohio State), MIFPA (Texas A&M), CNPQ, FAPERJ, FINEP (Brazil), DFG (Germany) and the Collaborating Institutions in the Dark Energy Survey.

The Collaborating Institutions are Argonne Lab, UC Santa Cruz, University of Cambridge, Ciemat-Madrid, University of Chicago, University College London, DES-Brazil Consortium, University of Edinburgh, ETH Zürich, Fermilab, University of Illinois, ICE (IEEC-CSIC), IFAE Barcelona, Lawrence Berkeley Lab, LMU München and the associated Excellence Cluster universe, University of Michigan, NOAO, University of Nottingham, Ohio State University, University of Pennsylvania, University of Portsmouth, SLAC National Lab, Stanford University, University of Sussex, Texas A&M University, and the OZDES Membership Consortium.

The DES Data Management System is supported by the NSF under grant number AST-1138766. The DES participants from Spanish institutions are partially supported by MINECO under grants AYA2012-39559, ESP2013-48274, FPA2013-47986, and Centro de Excelencia Severo Ochoa SEV-2012-0234. Research leading to these results has received funding from the ERC under the EU’s 7th Framework Programme including grants ERC 240672, 291329, and 306478.
