with the fact that there is very little difference in the rates of these compounds at this concentration of acid.

The isotope effect of 2.50 which is observed for compound 1 is similar to the value of 3.25 for compound 6 at higher acities indicating an ASE2 mechanism. However, if we assume that the rate of compound 6 at $H_0 = 0$ in $D_2$SO$_4$ represents the rate at which all of the compounds react in this acidity by the normal ester mechanism, then we can calculate the isotope effect due just to the ASE2 mechanism for compound 1. This assumption seems quite warranted by the fact that at $H_0 = 0$ compounds 3-6 all react at virtually the same rate in $H_2$SO$_4$ and that they all have similar isotope effects. Furthermore, a deuterated medium will favor the normal mechanism even more. It is also necessary to assume an isotope effect of 0.75 for this mechanism which also seems borne out by Table IV. Using these values the isotope effect due solely to the ASE2 mechanism for compound 1 is 3.10. A similar calculation for compound 2 gives a value of 2.42.

Compound 2 is an interesting case at $H_0 = 0$. Using the rate for compound 6 as an approximation to the normal ester rate it can be shown that in $D_2$SO$_4$ the rate is 67% due to the normal ester mechanism, and only 33% due to the ASE2 mechanism. However, in $H_2$SO$_4$ the predominant mechanism is ASE2 (62% of the rate). Here is a situation where the predominant mechanism depends on whether the solvent is $H_2$O or $D_2$O.

There is one more mechanism (eq 9-12) which is a formal possibility and must be eliminated. This involves a protonation of the ester oxygen and then cleavage to the corresponding vinyl cation. As this mechanism does not involve water in the rate-determining step it would be expected to have an acidity dependence similar to the ASE~ mechanism. It would also have a rather sharp dependence on substituent. However, the isotope effect would have to be inverse since it involves a pre-equilibrium protonation. There is no portion of the acidity range in which all of these requirements are simultaneously satisfied for any of the compounds studied.

Another way of eliminating this possibility is by examination of the relative stabilities of the α-phenyl vinyl cation and the benzyl cation. The SN1 rate of solvolysis of PhCBr=CH$_2$ in 80% EtOH at 170°C is $6.0 \times 10^{-6}$ sec$^{-1}$ whereas the SN1 rate of solvolysis of PhCH$_2$Br in 90% EtOH at 30°C may be calculated to be approximately $1.2 \times 10^{-6}$ sec$^{-1}$.

Thus, it can be readily seen that PhCH$_2^+$ is a much more stable entity than PhC=H=CH$_2$. However, the hydrolysis of benzyl acetate by cleavage to the benzyl cation does not become significant until about 65% sulfuric acid. At 65% H$_2$SO$_4$ the rate is $1.7 \times 10^{-6}$ sec$^{-1}$. Therefore, the rate of α-acetoxyxystyrnes by this mechanism would be even slower by several orders of magnitude. As the rate of α-acetoxyxystrene extrapolated to 65% H$_2$SO$_4$ is about 6.3 sec$^{-1}$, this mechanism is completely excluded.

Kinetics of the Cerium (IV) Oxidation of Benzaldehyde

Kenneth B. Wiberg and Peter C. Ford

Contribution from the Department of Chemistry, Yale University, New Haven, Connecticut 06520. Received August 15, 1968

Abstract: The kinetics of the cerium (IV) oxidation of benzaldehyde to benzoic acid were studied in 85% aqueous acetic acid. The first reaction was the formation of a 1:1 benzaldehyde-ceric ion complex. This was followed by an acid-catalyzed decomposition of the complex as well as of a 2:1 benzaldehyde-ceric ion complex which is present in relatively low concentration. Evidence was found for the formation of benzoyl radicals as an intermediate, and the reaction was found to give a kinetic isotope effect.

Cerium(IV) is one of a group of metal ion oxidants which apparently react only via one-electron steps. Thus, in the oxidation of thallium(I) by ceric nitrate, kinetic results indicate the intermediacy of the highly unstable thallium(II) species rather than a two-electron step leading to cerium(II). The oxidation of chromium(III) to chromium(VI) by ceric sulfate was also shown to proceed via consecutive one-electron steps.

A typical mode of oxidation of aliphatic aldehydes and ketones by one-electron metal ion oxidants involves coordination with the carbonyl group followed by the

loss of an α-hydrogen. The organic intermediate reacts with a second equivalent of the oxidant to give an acetol, a ketol, or related compound.

\end{align*}
\]

As a result, nonenolizable aldehydes such as benzaldehyde and pivaldehyde are not easily oxidized by many of these reagents.

Cerium(IV) was of interest to us since it is readily reduced by benzaldehyde. Thus, we have carried out an investigation of the reaction in aqueous acetic acid solution. The stoichiometry of the reaction was first determined by allowing 0.23 M ceric perchlorate in 47% acetic acid to react with an excess of benzaldehyde. Except for a very small amount of a brownish substance, the only organic products were benzoic acid and unreacted benzaldehyde. Based on the expected 2:1 stoichiometry, the yield of isolated benzoic acid was 89%. The possibility that some benzil might be formed as a product was checked by an isotope dilution experiment using benzaldehyde-7-14C as the substrate. The maximum yield of benzil was found to be 0.019%.

The kinetic studies were carried out in 85% aqueous acetic acid and the rate of disappearance of cerium(IV) was determined both spectrophotometrically and titrimetrically. The aldehyde and ceric solutions were thoroughly degassed before mixing since oxygen was found to have a marked effect on the rate of reaction. Ceric perchlorate was used as the oxidant and perchloric acid was used as the catalyst since the perchlorate ion appears not to form stable complexes with cerium(IV).

Nitrate ion, which does form complexes with cerium(IV), was found to markedly retard the reaction.

The results from a typical titrimetric run carried out in the presence of excess benzaldehyde and perchloric acid are shown in Figure 1. The linearity of the rate plot indicates the reaction be first order in oxidant. This characteristic of the kinetic data proved to be consistent over a 12-fold range in perchloric acid concentration which gave a 60-fold range in the pseudo-first-order rate constant, \(k_{\text{ox}}\).

The results from typical spectrophotometric runs carried out at different perchloric acid concentrations are shown in Figures 2–4. At the lower acid concentrations, 0.1 M or less, the first-order plots are quite good (ignoring for the moment the initial rapid decrease in absorbance), and the slopes of the plots are equivalent to the titrimetric rate constants. In contrast, at higher acid concentrations, the curvature of the plots is very severe and the slopes of the level portion of the curves are wavelength dependent and less than the titrimetric rate constants (Table I). At lower wavelengths, the spectrophotometric rate constant approaches the titrimetric value; however, below 380 nm interference by the benzaldehyde spectrum prevented determination of reaction rates.

Several complications of the reaction system tended to give less than ideal reproducibility. Oxygen strongly

Wiberg, Ford | Cerium(IV) Oxidation of Benzaldehyde
accelerated the reaction and as a consequence very careful degassing was required. In a typical experiment the pseudo-first-order constant decreased from 93 × 10⁻² sec⁻¹ in the presence of oxygen to 1.14 × 10⁻² sec⁻¹ after two degassing cycles, and to 0.55 sec⁻¹ after four cycles. Cerium(IV) solution had only limited stability in aqueous acetic acid, and as a result, these had to be made up on the same day the kinetic experiments were performed. The reproducibility is indicated by the data in Table II which correspond to a single set of concentrations.

* [Ce(IV)] = 0.0052 M; [HClO₄] = 0.05 M; [C₆H₅CHO] = 0.025 M, μ = 0.6; 85% aqueous HOAc, 25°C.

The initial rapid decrease in absorbance apparent in Figures 3 and 4 was observed in all kinetic runs where the acid concentration exceeded 0.07 M. Evidence that this rapid absorbance change does not represent an oxidation comes from a comparison of titrimetric runs with spectrometric runs at the same acid concentration (Figures 1 and 4). A spectrometric run under the same conditions in the absence of benzaldehyde gave no comparable decrease in absorbance but rather gave a small increase due to the dissociation of the polymeric ceric species to correct for the dilution effect.

Since the initial absorbance change does not involve oxidation, but does involve both cerium(IV) and benzaldehyde, it appears probable that a complex is formed between the two reactants. The absorbance of the solution after complex formation has occurred, but before significant oxidation has occurred, may be estimated from the intersection of the lines in Figure 4. This value divided by the ceric concentration gives the apparent absorbancy index (εₑₑₑ) for the equilibrium mixture of complexed and noncomplexed cerium(IV). The magnitude of εₑₑₑ shows little change over a 12-fold variation in acid concentration (Table III and Figure 5) whereas the initial absorbancy index (εᵰ) nearly triples.

[Ce(IV)] = 0.0051 M; [C₆H₅CHO] = 0.025 M; μ = 0.6, 85% HOAc, 25°C.

These data indicate either that the equilibria constituting complex formation are relatively insensitive to changes in acid concentration or that complex formation is so favored that changes in the equilibrium do not influence εₑₑₑ. Although changes in acid concentration had little effect on εₑₑₑ, changes in benzaldehyde concentration have a large effect (Figure 6). These data suggest that complex formation is essentially complete at 0.05 M benzaldehyde.

Our previous investigation of ceric ion equilibria in aqueous acetic acid indicated that the principal species are the monomer and trimer, and that the species with a high absorbancy index is the monomer. The increase in εᵰ with increasing acid concentration results from a shift in the monomer–trimer equilibrium which responds to the cube of the acid concentration. The constant for the above equilibrium and the absorbancy indices are available from this investigation.
The equilibrium constant for benzaldehyde complex formation was estimated using the following model.

$$3M \xrightleftharpoons{K_1} \frac{K_2}{K_1} T$$

$$\text{C}_8\text{H}_6\text{CHO} + M \xrightleftharpoons{K_2}{K_1} \text{C}$$

$$[\text{Ce(IV)}]_{\text{tot}} = 3[T] + [M] + [C]$$

$$\varepsilon_{\text{eq}}[\text{Ce(IV)}]_{\text{tot}} = \varepsilon_T[T] + \varepsilon_M[M] + \varepsilon_C[C]$$

where $[\text{Ce(IV)}]_{\text{tot}}$ is the total number of equivalents of cerium(IV), $T$ is the trimer, $M$ is the monomer, and $C$ is the complex. Using the definitions of the equilibrium constants, the equations may be rewritten as

$$[\text{Ce(IV)}]_{\text{tot}} = 3K[T] + K[M][\text{C}_8\text{H}_6\text{CHO}] + [M]$$

$$\varepsilon_{\text{eq}}[\text{Ce(IV)}]_{\text{tot}} = \varepsilon_TK[T] + \varepsilon_M[M] + \varepsilon_C[M]$$

giving

$$0 = [(3 - \varepsilon_T)/\varepsilon_C]K[T]^3 + [(1 - \varepsilon_M)/\varepsilon_C][M] - [(1 - \varepsilon_M)/\varepsilon_C][\text{Ce(IV)}]_{\text{tot}}$$

At higher aldehyde concentrations, the cubic term in monomer concentration will be negligible in comparison to the first-order term. Then

$$[M]/[\text{Ce(IV)}]_{\text{tot}} = [(1 - \varepsilon_M)/\varepsilon_C][1 - \varepsilon_M]/\varepsilon_C]$$

The value of $\varepsilon_C$ may be estimated from Figure 6 to be 0.25 at 420 mμ, and $\varepsilon_M$ can be calculated from the data in ref 5 as approximately 350. Using the value of $\varepsilon_{\text{eq}}$ found with 0.025 M benzaldehyde, one calculates that 91% of the ceric ion is in the form of the complex.

The initial change in absorbance corresponds to the change of monomeric ceric species to the complex having a lower absorbancy index. It seems reasonable to assume that the complex is formed by the reaction of the monomer with the aldehyde. If this is correct, the rate constant for the complex formation may be estimated. The model used is

$$\text{T} \xrightarrow{k_1/k_{-1}} \text{3M}$$

$$\text{M} + \text{C}_8\text{H}_6\text{CHO} \xrightarrow{k_1/k_{-1}} \text{complex C}$$

The change in absorbance ($\Delta A$) with time would be given by

$$\frac{d\Delta A}{dt} = \epsilon_M \frac{d[M]}{dt} + \epsilon_T \frac{dT}{dt} + \epsilon_C \frac{dC}{dt}$$

$$\epsilon_T = (3\epsilon_M - \epsilon_T)(k_1[T] - k_{-1}[M]^3) + (\epsilon_C - \epsilon_M) \times (k_2[M][\text{C}_8\text{H}_6\text{CHO}] - k_{-1}[C])$$

Since at time zero, $k_1[T] = k_{-1}[M]^3$ and $[C] = 0$, the initial rate would be

$$\frac{d\Delta A}{dt} = -(\epsilon_M - \epsilon_C)k_2[M][\text{C}_8\text{H}_6\text{CHO}]$$

The initial velocities could be determined by plotting the average rate of absorbance change, $(A_0 - A_1)/t$, against time and extrapolating to zero time. In practice, it was found more convenient to plot the logarithm of this quantity against time giving nearly linear plots (Figure 7) from which the zero time intercept was more easily estimated.

The effect of acid concentration on the initial rates of complex formation was investigated giving the data in Table IV. Since the change in acid concentration also affects the ratio of monomeric to trimeric cerium species, this was taken into account by dividing the initial rates by the monomer concentration calculated from our equilibrium constants. The resultant data are plotted against the acid concentration in Figure 8 and it can be seen that there is a linear relationship. Thus, the rate of complex formation appears to have a first-order dependence on hydrogen ion concentration.
The effect of benzaldehyde concentration on the rate of complex formation also was investigated giving the data in Table V. Although the initial rates increase with increasing benzaldehyde concentration, they do not rise as rapidly as the aldehyde concentration. This behavior suggests a rate law of the type

\[
(d[M]/dt)_i = A[M][RCHO]/(1 + B[RCHO])
\]

A plot of the initial rate against \(1/[RCHO]\) should then be linear giving a slope of \(1/A[M]\) and an intercept of \(B/A[M]\). Figure 9 shows this expectation to be realized.

\[ a[Ce(IV)] = 0.0050 \ M, \ \text{HClO}_4 = 0.30 \ M, \ \mu = 0.6, \ \text{85}\% \ \text{HOAc}, \ 420 \ \text{m}\mu, \ 25.0^\circ. \]

With increasing benzaldehyde concentration, they do not rise as rapidly as the aldehyde concentration. This behavior suggests a rate law of the type

\[
(d[M]/dt)_i = A[M][RCHO]/(1 + B[RCHO])
\]

where \(A\) and \(B\) are constants. Figure 9 shows this expectation to be realized.

A mechanism consistent with this rate law would involve the reaction of benzaldehyde with a ceric monomer which is in a small steady-state concentration and is formed from the predominant form of the ceric monomer by an acid-catalyzed reaction.

\[
M + H^+ \xrightarrow{k_a} M' + H^+
\]

The initial velocity of complex formation would be

\[
(d[C]/dt)_i = k_a[M'][RCHO]
\]

Applying the steady-state approximation to \(M'\)

\[
(d[M']/dt)_i = 0 = k_a[M'][H^+] - k_{-a}[M'] - k_b[M][RCHO]
\]

\[
[M'] = k_a[M][H^+]/(k_{-a} + k_b[RCHO])
\]

then

\[
(d[C]/dt)_i = \frac{k_bk_a[M][RCHO][H^+]}{k_{-a} + k_b[RCHO]}
\]

The initial rate of disappearance of monomeric cerium(IV) must equal the rate of formation of complex.
Thus, this expression is of the form required by the experimental data, where \( A = k_a k_b [\text{H}^+]/k_{-a} \) and \( B = k_b/k_{-a} \).

The first-order term in acid concentration suggests that \( M = \text{CeOR}^3+ \) and \( M' = \text{Ce}^4+ \).

\[
\text{CeOR}^3+ + \text{H}^+ \xrightleftharpoons{k_b}{k_{-b}} \text{Ce}^4+ + \text{OR}^- + \text{H}_2\text{O}
\]

where \( \text{OR}^- \) is either \( \text{OAc}^- \) or \( \text{OH}^- \). By combining this step with complex formation

\[
\text{Ce}^4+ + \text{R'CHO} \xrightarrow{k_z}{k_{-z}} \text{C}
\]

the rate law becomes

\[
\frac{d[M]}{dt} = \frac{k_1 k_2 [\text{H}^+] [\text{R'CHO}] [M]}{k_{-a} [\text{ROH}] + k_4 [\text{R'CHO}]}
\]

The intercept in Figure 9 (4.95 \( \times \) 10\(^{-3}\) mol l\(^{-1}\) sec\(^{-1}\)) equals \( 1/k_3 [\text{H}^+] \) giving \( k_3 = 0.431 \) l mol\(^{-1}\) sec\(^{-1}\). The slope in Figure 9 (6.07 \( \times \) 10\(^{-3}\) sec\(^{-1}\)) equals \( k_{-a} [\text{ROH}]/k_2 [\text{H}^+] [M] \). Knowing \( k_2 \), the ratio \( k_{-a} [\text{ROH}]/k_2 \) is found to be 0.123 M. The product \( k_{-a} [\text{ROH}] \) may be treated as a single constant, \( k_{-a}' \), as long as the solvent composition is not changed.

The values of \( k_{-a} \) and \( k_2 \) cannot be determined unless one knows the value of \( k_1/k_{-a}' \). This ratio was estimated using the equilibrium constant for the hydrolysis of \( \text{Ce}^4+ \) in water \( ^6 \)

\[
\text{Ce}^4+ + \text{H}_2\text{O} \rightleftharpoons \text{CeOH}^3+ + \text{H}^+ + \text{H}_2\text{O}
\]

and the constant for the equilibrium \( ^3 \)

\[
\text{CeOH}^3+ + \text{HOAc} \rightleftharpoons \text{CeOAca}^4+ + \text{H}_2\text{O}
\]

The former equilibrium constant is 5.2 mol/l. in water, but a correction for the concentration of water in 85% acetic acid (ignoring the probable changes in activity coefficients) gives a value of 0.81 mol/l in this solvent. The latter equilibrium has a constant of 5.7 in aqueous HOAc. Combination of these two gives

\[
0.185 \text{ l/mol} = k_3/k_{-a}' = \frac{[\text{Ce}^4+]}{[\text{H}^+]}\frac{[\text{M}]}{[\text{H}^+]}
\]

where \([\text{M}] = [\text{CeOH}^3+] + [\text{CeOAca}^4+]\). Although this is at best a very rough estimate, it will be useful in a following comparison. Based on this constant \( k_{-a}' = 2.32 \text{ sec}^{-1} \) and \( k_3 = 18.9 \text{ l mol}^{-1} \text{ sec}^{-1} \).

The slope of the curve in Figure 8 which gives the effect of perchloric acid on the rate was 0.0736 l mol\(^{-1}\) sec\(^{-1}\). This should equal \( k_1 k_2 [\text{RCHO}]/(k_{-a}' + k_3 [\text{RCHO}]) \). Using the above values and [RCHO] = 0.025 M, the slope was calculated to be 0.0729 indicating the internal consistency of the rate constants which were derived.

The kinetics of the oxidation step may now be considered. The titrimetric method unambiguously measures the rate of disappearance of cerium(IV) species. The linearity of \( \ln (V_1 - V_2) \) vs. time plots over a wide range of acid concentration (0.025-0.30 M) strongly implies that the oxidation is first order in cerium(IV) despite the possible complication from the monomer-trimer equilibrium. This conclusion is consistent with the assumption that the complex is the species involved in the oxidation step. The induction period noted in the titrimetric runs (Figure 1) also is in agreement with this assumption.

![Figure 10](image-url) Effect of acid concentration on the titrimetric rate of oxidation, [C\(_2\)H\(_4\)CHO] = 0.025 M.

The effect of acid concentration on the titrimetric oxidation rate is recorded in Table VI. It can be seen that there is not a simple first-order dependence. A plot of \( k_3/[\text{HClO}_4] \) against \([\text{HClO}_4]\) (Figure 10) gave a linear relationship indicating both first- and second-order terms

\[
v_{ox} = k_3 [\text{H}^+][\text{Ce}^4+] + k_4 [\text{H}^+]^2 [\text{Ce}^4+]
\]

where \( k_3 [\text{H}^+] + k_4 [\text{H}^+]^2 = k_{ox} \).

The effect of benzaldehyde concentration on the reaction rate is relatively complex. At 0.05 M perchloric acid, an increase in benzaldehyde concentration led to a decrease in reaction rate (Table VII). In contrast, changes in concentration had little effect on the rate at 0.1 M perchloric acid. Finally, at 0.3 M perchloric acid, an increase in benzaldehyde concentration led to an increase in the rate constant.

The data for 0.3 M perchloric acid yields a linear plot of \( 1/k_{ox} \) against \( 1/[\text{RCHO}] \) (Figure 11) suggesting a rate law of the form

\[
v = k_{ox} [\text{Ce}^4+] = \frac{A [\text{RCHO}][\text{Ce}^4+]}{1 + B [\text{RCHO}]}
\]

This behavior is typical of a mechanism proceeding via partial equilibrium formation of some intermediate species prior to the rate-determining step. However, the preceding evidence indicates that essentially all of the Ce(IV) is in the form of an aldehyde
An appropriate rate law may be derived as follows

Concentrations may reflect a rate law such as

\[ \text{Combined with the different effects of changing substrate} \]

and titrimetric runs. Data are given.

Where having two aldehydes associated with cerium(IV)

Figure 11. Effect of benzaldehyde on the titrimetric rate of oxidation, \([\text{HClO}_4]\) = 0.3 M.

The oxidation rate has both a first-order term and a second-order term in acid concentration. This fact, represented in the above equation cannot be a result of the first benzaldehyde Ce(IV) complex as oxidation proceeding via disproportionation of this species would be expected to give zero-order kinetics with respect to aldehyde concentration.

The data then suggest that a second complex is formed having two aldehydes associated with cerium(IV)

[Ce(IV)] = \([C_2] + K_3[C_2][\text{RCHO}]\)

\[ C_1 = \frac{[\text{Ce(IV)}]}{1 + K_2[\text{RCHO}]} \]

\[ C_2 = \frac{K_3[\text{Ce(IV)}][\text{RCHO}]}{1 + K_4[\text{RCHO}]} \]

\[ v = \frac{k_1[H^+][\text{Ce(IV)}] + k_2K_2[H^+][\text{RCHO}][\text{Ce(IV)}]}{1 + K_4[\text{RCHO}]} \]

At a sufficiently low acid concentration, \(k_4[H^+] > k_2K_2[H^+][\text{RCHO}]\), and increasing benzaldehyde concentration will depress the rate because of the aldehyde term in the denominator. At higher acid concentrations, \(k_3K_3[\text{RCHO}][H^+] > k_1[H^+]\) and the second term in the rate law will dominate the kinetic behavior. The relative contributions of the two pathways may be estimated from the results of Figure 10. The intercept corresponds to \(k_2(1 + K_2[\text{RCHO}])\) and equals 0.15 \(\times 10^{-2}\) 1. mol\(^{-1}\) sec\(^{-1}\) and the slope corresponds to \(k_3K_3[\text{RCHO}][1 + K_4[\text{RCHO}]]\) and equals 2.70 \(\times 10^{-2}\) 1. mol\(^{-1}\) sec\(^{-1}\). At 0.05 M benzaldehyde, the intercept is 0.11 and the slope is 3.60 \(\times 10^{-2}\). From these values we calculate \(k_2 = 0.315 \times 10^{-2}\) 1. mol\(^{-1}\) sec\(^{-1}\), \(k_3 = 5.4 \times 10^{-3}\) 1. sec\(^{-1}\), and \(K_2 = 40\) l. mol\(^{-1}\). Using these values, the observed oxidation rate constant may be calculated from

\[ k_{ox} = \frac{k_1[H^+] + k_2K_2[H^+][\text{RCHO}]}{1 + K_4[\text{RCHO}]} \]

The calculated values are summarized in Table VII, and it can be seen that the agreement is good except for the higher aldehyde concentrations at 0.05 M perchloric acid.

The effect of solvent composition on the rate of oxidation was determined giving the data in Table VIII. The effect is surprisingly small considering the great sensitivity of the reaction toward changes in acid concentration. For the perchloric acid concentration used to obtain the data in Table VIII, the Hammett acidity parameter, \(h_0\), increases by a factor of about 3.5 over this solvent range. Since the rates do not increase in the fashion predicted from the second-order acid terms in the rate law, it is apparent that the small effect from changing the reaction medium is the result of opposing influences.

Table VII. Effect of Benzaldehyde Concentration of the Rate of Oxidation*

* \([\text{Ce(IV)}] = 0.0050 M, \mu = 0.6, 85\% \text{ HOAc}, 25.0^\circ\). The rate constants for 0.05 and 0.1 M acid are the average for spectrometric and titrimetric runs. At 0.3 M perchloric acid, only the titrimetric data are given.

The data then suggest that a second complex is formed having two aldehydes associated with cerium(IV)

[Ce(IV)] + RCHO \(\rightarrow\) C1

C1 + RCHO \(\rightarrow\) C2

where \(K_1 \gg K_2\).

The oxidation rate has both a first-order term and a second-order term in acid concentration. This fact, combined with the different effects of changing substrate concentration on the reaction velocity at different acid concentrations may reflect a rate law such as

\[ v = k_1[H^+][C_1] + k_2[H^+]^2[C_1] \]

An appropriate rate law may be derived as follows

\[ [\text{Ce(IV)}]_{\text{total}} = [C_1] + [C_2] \]

\[ K_2 = \frac{[C_2]}{[C_1][\text{RCHO}]} \]

Substituents attached to the benzaldehyde ring were found to retard the rate of oxidation regardless of the sign of the Hammett \(\sigma\) value (Table IX). Similar decreases in the relative oxidation rate for both substituents were noted for spectrophotometric runs done at 0.30 M [H\(^+\)]. In each case, \(k_{ox}\) for the substituted
benzaldehyde was greater than that for benzaldehyde suggesting that at least part of the rate reduction was due to decreases in the formation constants for the initial complexes.

* $[\text{Ce(IV)}] = 0.0050$ M, $[\text{H}^+] = 0.10$ M, $[\text{RCHO}] = 0.025$ M, $\mu = 0.6, 85\%$ HOAc.

Since a carbon–hydrogen bond is cleaved during the reaction, the kinetic hydrogen isotope effect was examined. Benzaldehyde-d was prepared as described previously, and was found to contain 0.986 of a deuterium. With 0.1 M perchloric acid, and 0.025 M benzaldehyde-d, the titrimetric rate constant was 0.026 $\times 10^4$ sec$^{-1}$ and the spectrometric rate constant was 0.023 $\times 10^4$ sec$^{-1}$ giving $k_{\text{D}}/k_{\text{H}} = 16$.

The reaction between benzaldehyde and a one-electron oxidant such as cerium(IV) might be expected to proceed with the intermediate formation of free radicals. In agreement with this, it was found that the oxidation of triphenylacetaldehyde by ceric perchlorate in aqueous acetic acid gave exclusively triphenylcarbinol and carbon monoxide. Richardson also found that the cerium(IV) oxidation of benzaldehyde induced the polymerization of acrylamide whereas in the absence of benzaldehyde, cerium(IV) leads only to very slow polymerization. Induced polymerization of acrylic monomers has been widely applied in systems where free-radical intermediates are possible.

It seemed of importance to determine which species acted as the initiator. If it were the benzoyl radical, each polymer chain should contain one or two benzoyl end groups depending on the mechanism of termination. Thus, the cerium(IV) oxidation of benzaldehyde$^{14}$C was carried out in the presence of 0.6 M acrylonitrile. The voluminous white precipitate was collected and was purified by dissolving it in dimethylformamide and reprecipitating by adding water. The activity was not changed by the second reprecipitation. The results are summarized in Table X.

* $[\text{Ce(IV)}] = 0.0050$ M, $\mu = 0.6$, [acrylonitrile] = 0.6 M, 85% HOAc, 25°, total volume = 250 ml, RCHO had 39.0 $\mu$Ci/g.

Even if one assumes that the yield of polymer from the work-up was as low as 50%, the maximum yield of trapped free radicals is only 7%. Therefore, either Ce(IV) is a much better radical trap than acrylonitrile, or the nature of the reaction proceeds via a radical pathway, or the method of isolation and purification led to loss of a considerable part of lower molecular weight polymer. The last possibility is not unreasonable for cerium(IV) could act as a radical trap and terminate polymerization with a relatively short chain length. It might be noted that the activity of the polymer dropped to half after the first reprecipitation.

In order to determine the fraction of a benzoyl group on monomer chain, the molecular weight distribution of the polymer was determined. The average molecular weight was 48,600, and less than 1% of the polymer had a molecular weight less than 3000. Integrating the product of the benzaldehyde activity (4.1 $\times 10^{3}$ Bq/mol) and the weight fraction divided by the molecular weight over the molecular weight distribution gave a calculated activity of 0.074 Bq/g. Considering the errors associated with determining the molecular weight distribution, the calculated value is in good agreement with the observed values indicating that each polymer chain has one benzoyl group.

All of the data given above appear consistent with the mechanism

\[

T &\xrightarrow{k_1} 3M \\
H^+ + M &\xrightarrow{k_2} Ce^{1+} + HOR \\
Ce^{1+} + R'CHO &\xrightarrow{k_3} C_2 \\
C_1 + R'CHO &\xrightarrow{k_4} C_2 \\
C_2 + 2H^+ &\xrightarrow{k_5} R'CO\cdot + Ce(III) \\
R'CO\cdot + Ce(IV) &\xrightarrow{k_6} R'COH + Ce(III)
\end{align*}
\]

The kinetic isotope effect indicates steps 5 and 6 to involve rate-determining C−H bond cleavage. The rate constants in the series have been derived and are summarized in Table XI. The last step is presumably a rapid one which follows the rate-determining step, and therefore no information is available concerning its magnitude. However, $k_5$ must be quite large so that this reaction will be competitive with the capture of the benzoyl radical by acrylonitrile.

The large rate retardation found on the addition of nitrate ion presumably occurs because nitrate ion will compete with the aldehyde in step 3.

Experimental Section

Reagents. All solid inorganic reagents were converted to the anhydrous form before using by heating at 110°C. The sodium perchlorate was tested for chloride ion with silver nitrate solution and for chloride with acidic iodide solution. When either was found, the material was purified by recrystallization from water.

Perchloric acid was reagent grade. Cerium(IV) perchlorate was obtained from the G. F. Smith Chemical Co. as an approximately 0.5 M solution in 3 M perchloric acid. The ceric ion concentration was determined by titration with sodium thiosulfate solution to a starch–iodine end point. The acid concentration was determined by dissolving samples in acetic acid, adding an excess of acetic anhydride to remove water, and titrating potentiometrically with a standard solution of sodium acetate in glacial acetic acid.

Acetic acid was purified by heating with chromic acid followed by vacuum distillation. The water content was determined spectrophotometrically using acetic anhydride.11 Water was purified by distillation from chromic acid.

Benzaldehyde was purified immediately before use by distillation under reduced pressure under a nitrogen atmosphere. A center cut was taken, and was kept under nitrogen. The substituted benzaldehydes were commercial samples. The liquid aldehydes were distilled using the same procedure as for benzaldehyde and the solid aldehydes were recrystallized twice from an ethanol-water mixture and then sublimed at 1 mm at a temperature 10°C below their melting point. Benzaldehyde-d was prepared as described previously, and was purified in the same fashion as for benzaldehyde. Benzaldehyde-14C was obtained from the New England Nuclear Corp. and was diluted with unlabeled aldehyde to give 3 g of aldehyde having 39.0 µCi/g as determined by liquid scintillation counting.

The Prevalence of cis-Addition Products in the Reaction of the Butenyl Grignard Reagent with Sterically Hindered Ketones

R. A. Benkeser, W. G. Young, W. E. Broxterman, D. A. Jones, Jr., and S. J. Plaseczynski

Contribution from the Departments of Chemistry, Purdue University, Lafayette, Indiana 47907, and the University of California, Los Angeles, California 90024. Received August 5, 1968

Abstract: The reactions of crotymagnesium bromide with ethyl isopropyl, disopropyl, isopropyl t-butyl, and di-t-butyl ketones have been examined under carefully controlled conditions. The quantity of α-methylallylcarbinol formed in each case was found to decrease and the amount of crotylcarbinol to increase progressively as the steric requirements of the alkyl groups attached to the carbonyl of the ketone increased. This observation probably reflects increasing steric hindrance in the transition state leading to α-methylallyl products. In all cases, the cis/trans ratio of the crotyl adducts was greater than unity, which can be explained by invoking the hypothesis that the cis form of the butenyl Grignard reagent is more thermodynamically stable than the trans form. Several mechanistic possibilities have been proposed to account for the results.

A great deal of work has appeared in the last 23 years concerning the structure and mode of reaction of the butenyl Grignard reagent. One of the more interesting reactions of this species is its facile addition to di-t-butyl ketone to give crotyledi-t-butylcarbinol in 69% yield.1 To our knowledge, this still remains as the only example of formation of a product which can be considered as derived from the primary form of the
