Magnetic Nanoparticle Adsorbents for Emerging Organic Contaminants

Yuxiong Huang and Arturo A. Keller*

INTRODUCTION

Recent attention has been directed at chemicals that are historically unregulated or not commonly regulated as contaminants but have the potential to enter the environment and cause known or suspected adverse ecological and human health effects, such as pharmaceuticals, personal care products, surfactants, various industrial additives, and endocrine disruptors, including hormones.1−3 These chemicals are collectively defined as emerging organic contaminants (EOCs) (http://toxics.usgs.gov/regional/emc). The presence of these synthetic chemicals in the wastewater or surface water may contaminate ecosystems and surface and drinking water supplies. Recent studies have shown that EOCs may have biological effects and even potential ecotoxicological impacts on invertebrates (such as daphnids), fish, algae, mussels, and also human embryonic cells.4−10 To date, most of the studies have focused on the occurrence and/or fate of EOCs in surface waters11−15 and/or wastewater.16−19 However, there are few studies on approaches to remove EOCs from aqueous media. Therefore, the development of technologies to remove legacy and emerging organic contaminants from water is of great importance.

In recent years, magnetic particles have received a lot of attention as powerful adsorbents because their inherent superparamagnetic properties make them desirable for magnetic field assisted separations.20−23 For instance, magnetic iron oxides (Fe₂O₃ and Fe₃O₄) have been reported as potential adsorbents for the removal of pollutants from aqueous media.24−27 The surface characteristics of the sorbents are very important to the effectiveness of the adsorption process. Because sorption of organic chemicals can be enhanced by coating of surfactants onto the sorbent, in a previous study we synthesized magnetic permanently confined micelle arrays (Mag-PCMAs) with a magnetic core and a silica porous layer that permanently confines surfactant micelles within the mesopores.28 The magnetic core allows for rapid separation of the Mag-PCMAs from solution by applying a magnetic field. Mag-PCMAs have been applied to the removal of very hydrophobic compounds29 and/or oxyanions.30

The objective of this study is to determine the effectiveness of Mag-PCMAs to remove EOCs from water. For comparison, two legacy contaminants (e.g., ethylbenzene, 2-chlorophenol) were also evaluated. The microenvironment of the interactions between the mesoporous layers of the Mag-PCMAs and the multiple binding sites on EOCs make it a significant study for sorbents in complex chemical environments, such as water treatment. Mag-PCMAs have low energy requirements in their synthesis, use, and regeneration, compared to other adsorbents such as granular activated carbon (GAC), resulting in a much more sustainable material.

MATERIALS AND METHODS

Chemicals. Tetramethyl ammonium hydroxide (TMAOH) (25 wt % in water), 3-(trimethoxysilyl)propyl-octadecyldimethylammonium...
ACS Sustainable Chemistry & Engineering

Research Article

carbonate (TPODAC) (72 wt % in methanol), ammonia (28%), methanol, tetraethyl orthosilicate (TEOS), atenolol, gemfibrozil, sulfamethoxazole, \( \nu \)-gluconic acid sodium salt, and succinic acid disodium salt were purchased from Sigma-Aldrich (St. Louis, MO, U.S.A.). Methyl orange and \( \nu \)-3-(3,4-dihydroxyphenyl)alanine (\( \nu \)-DOPA) were purchased from Acros Organics (Geel, Belgium). Ethylbenzene and 2-chlorophenol were purchased from Fisher Scientific (Pittsburgh, PA, U.S.A.). Maghemite iron(III) oxide nanoparticles (30 nm in diameter) were purchased from Alfa Aesar (Ward Hill, MA, U.S.A.). All chemicals were used as received, without further purification.

Relevant physico-chemical properties for the contaminants are presented in Table 1.

Synthesis of Mag-PCMAs. The synthesis procedure for Mag-PCMAs was improved compared to the previous study to improve yield and reduce the use of ethanol.\(^{28}\) The core–shell structured Mag-PCMAs were improved compared to the previous study to improve yield and reduce the use of ethanol.\(^{28}\) The core–shell structured Mag-PCMAs were improved compared to the previous study to improve yield and reduce the use of ethanol.\(^{28}\) The core–shell structured Mag-PCMAs were improved compared to the previous study to improve yield and reduce the use of ethanol.\(^{28}\) The core–shell structured Mag-PCMAs were improved compared to the previous study to improve yield and reduce the use of ethanol.\(^{28}\) The core–shell structured Mag-PCMAs were improved compared to the previous study to improve yield and reduce the use of ethanol.\(^{28}\) The core–shell structured Mag-PCMAs were improved compared to the previous study to improve yield and reduce the use of ethanol.\(^{28}\)

The concentration of the sample was measured at the end of 5, 15, 30, 60, 90, 120, and 180 min. Then the Mag-PCMAs particles with adsorbed contaminants were separated from the mixture with an Eclipse Magnetics N821 permanent hand-held magnet (50 mm ×50 mm ×12.5 mm; 243.8 g pull force: 40.1 N).

To develop adsorption isotherms, solutions with varying initial concentrations were treated with the same procedure as above at room temperature. The equilibration time was 24 h uniformly, which was determined to be sufficient to reach the adsorption equilibrium. Preliminary experiments indicated that more than 99% of adsorption occurred within the first 120 min. The contaminant concentrations ranged from 10 to 3000 mg/L, and the Mag-PCMAs concentration were 100 mg/L.

The solid-phase concentrations were determined by mass balance, according to eq 1

\[
q_e = \frac{V \times (C_0 - C_e)}{M}
\]

where \( C_0 \) and \( C_e \) are the initial and equilibrium concentration of EOC in the liquid phase (mg/L), respectively; \( q_e \) is the equilibrium concentration of contaminants adsorbed on the unit mass of Mag-PCMs (mg/g); \( V \) is the volume of solution, and \( M \) is the mass of dry Mag-PCMs (g).

Analysis by UV-Spectrophotometry and HPLC. Two instruments were used: a high performance liquid chromatography HPLC system (SPD-M10AVP, Shimadzu, MD) or a UV–vis spectrometer (BIOSPEC-1601, Shimadzu, MD). Each instrument was used to determine the final concentration of organic contaminants after adsorption occurred. HPLC was used for the analysis of \( \nu \)-DOPA. The HPLC system was equipped with two LC-10AT VP pumps, a Sil-10AF autosampler, DGU-14A degasser, and SPD-M10AVP diode-array detector. A TSKgel ODS-120A column (length, 250 mm; inner diameter, 4.6 mm) was used. The HPLC analyses were carried out with a mobile phase comprised of 30% methanol/70% water. The analyses were performed at a constant flow rate of 1.0 mL/min. The ultraviolet detector monitored the absorbance at 261 nm for \( \nu \)-DOPA. The UV–vis spectrometer was used to monitor the concentration of organics in water at the absorption maximum for each compound: methyl orange at 400 nm, ethylbenzene at 261 nm, 2-chlorophenol at 261 nm, 2-chlorophenol at 261 nm, and 2-chlorophenol at 261 nm.

40 mL of TMAOH solution (25% by weight) under constant mixing overnight to activate the surface. Then 0.5 mL of TPODAC, a cationic surfactant, was added to the maghemite suspension under constant stirring. Next, 5 mL of 28% ammonium hydroxide were added for base catalyzed sol–gel hydrolysis of TEOS (1.1 mL) to cross-link the surfactant onto the magnetic iron core. The three steps are done at room temperature (22 °C).

Scanning Electronic Microscopy. Scanning electronic microscopy (SEM) imaging was performed under vacuum on an FEI XL40 FEG digital scanning microscope using an accelerating voltage of 5.00 kV.

Batch Sorption of Emerging Organic Contaminants. Adsorption kinetics were determined by batch experiments. A total of 2.0 mg of Mag-PCMs was mixed with 20 mL of a given organic contaminant in 20 mL vials. The initial concentration of contaminant was 100 mg/L in all cases. All experiments were conducted at pH 7.0. These vials were shaken in an end-over-end shaker on Dayton-6Z2412A Parallel Shaft roller mixer with a speed of 70 rpm at room temperature. The concentration of the sample was measured at the end of 5, 15, 30,
Figure 4. Noncompetitive sorption onto Mag-PCMA across a concentration range for (A) atenolol, (B) D-glucose, (C) gemfibrozil, (D) sulfamethoxazole, (E) succinic acid, (F) L-DOPA, (G) methyl orange, (H) 2-chlorophenol, and (I) ethylbenzene. The solid lines represent model fits based on the best model for each compound.
Calibration curves were performed daily with a regression (relation between removal efficiency and octanol-water partitioning coefficient) to provide a better control their affinity for the cationic TPODAC surfactant. In general the amount sorbed decreases with increasing $K_{ow}$ (Figure 5), with l-DOPA and d-glucronic acid representing major outliers. The large number of –OH groups on both of these compounds results in very different behavior than the other compounds studied. The trend is much less conclusive than for a sequence of hydrophobic organic contaminants where in fact adsorption increases with hydrophobicity. For ionizable compounds, their adsorption onto Mag-PCMAs generally increases with $pK_a$ (Figure 6), although the behavior is not easily predictable based on this physicochemical characteristic alone. Further work will be done with a broader range of compounds to elucidate more clearly the relationships.

For non-ionic compounds, removal was strongly correlated with the $K_{ow}$ of the compounds, a common indicator of hydrophobicity (Figure 6). In general, removal rate was found to decrease with hydrophobicity, except for ethylbenzene. Repeated adsorption experiments for ethylbenzene results in very different behavior than the other compounds studied. The trend is much less conclusive than for a sequence of hydrophobic organic contaminants where in fact adsorption increases with hydrophobicity. For ionizable compounds, their adsorption onto Mag-PCMAs generally increases with $pK_a$ (Figure 6), although the behavior is not easily predictable based on this physicochemical characteristic alone. Further work will be done with a broader range of compounds to elucidate more clearly the relationships.

### Results and Discussion

**Mag-PCM Characterization.** SEM images show the hydrated particles are 600 nm to 1 μm in size (Figure 2). Figure 3 presents the separation of Mag-PCMAs from the suspension using a simple magnet. The dispersed Mag-PCMAs can be separated within a few seconds from the suspension, with a very high recovery of the Mag-PCMAs. The energy requirements for the separation of the magnetic particles is minimal, particularly if a permanent magnet is used.

**Noncompetitive Sorption Studies.** Figure 4 presents the experimental results for the noncompetitive sorption for each compound for the range of concentration studies, as well as the fit of a Freundlich isotherm, linearized by taking the logarithm of both sides of the equation:\(^{(31)}\)

$$\log q = \log K_f + n \log C_e$$

where $q$ is the amount of contaminant adsorbed at equilibrium (mg/g); $C_e$ is the equilibrium concentration of contaminant in solution (mg/L); $K_f$ is the Freundlich adsorption constant (mg$^{1-n}$ g$^{-1}$ L$^n$); and $n$ is a measure of adsorption intensity (dimensionless). The Freundlich parameters $K_f$ and $n$ were determined from the intercept and slope of eq 2. Table 2 summarizes the fitted values from all compounds. The Freundlich isotherm was used because it provided a better fit than linear or Langmuir models. Additionally, 2-chlorophenol, ethylbenzene, succinic acid, and l-DOPA were fitted using a nonlinear exponential model\(^{(32)}\) to provide a better fit

$$\log q = n \log C_e + n_2(\log C_e)^2 + \log K_f$$

On the basis of the equilibrium sorption concentrations, $q$, at a given $C_e$ Mag-PCMAs exhibited the highest sorption capacity for l-DOPA and the lowest for d-glucronic acid. While for more conventional non-ionic and contaminants such as petroleum hydrocarbons and chlorinated solvents, there is a strong correlation between removal efficiency and the octanol–water partitioning coefficient ($K_{ow}$),\(^{(28)}\) and for anionic compounds removal efficiency can be predicted by their Gibbs free energy of adsorption.\(^{(30)}\) The EOC present multiple characteristics that

given the high sorption capacity for this compound. Sorption occurred rapidly, even for an initial concentration of 100 mg/L. Within the first 60 min, almost all of the methyl orange was adsorbed, with minimal additional sorption after 2 h (Figure 7A).

Figure 7B shows the evident color change in the mixture solution with the passage of time indicating the concentration of methyl orange decreased quickly. Note that the image was made after concentrating the Mag-PCMAs at the bottom of the vial using a permanent magnet.

■ CONCLUSIONS

Mag-PCMAs with a core−shell structure are fast, convenient, and efficient sorbents for removing rather soluble organic contaminants from water. This study has extended the application of Mag-PCMAs from removing very hydrophobic compounds, natural organic matter, and oxyanions to consider emerging organic compounds, including pharmaceuticals and personal care compounds. The most likely mechanisms of adsorption of organic contaminants onto Mag-PCMAs are hydrophobic interactions, hydrogen bonding, and electrostatic interactions. Because all of these mechanisms are at play for these mixed functionality compounds, it is not easy to predict the adsorption capacity simply on the basis of one physicochemical property (e.g., $K_{ow}$ or $pK_a$). Further work will be done with a broader range of compounds to elucidate more clearly the relationships.

The synthesis procedure for Mag-PCMAs is simple and requires low energy and relatively low cost (~$4/kg), and the Mag-PCMAs with adsorbed organic contaminants can be easily removed from water via magnetic separation. This can be compared to carbon nanotubes (CNTs) that have been considered as adsorbents, with a cost of $500−1000/kg. This is in part because manufacturing CNTs requires high pressure and temperature, i.e., considerable energy. Granular activated carbon (GAC) is less than $1/kg, but synthesis of GAC requires heating the carbon source several hundreds of degrees to activate the carbonaceous surface. Increasing the input energy can shorten the time needed for equilibrium. The regeneration of Mag-PCMAs, presented in previous studies, can be done at room temperature using ethanol or methanol to desorb the low $K_{ow}$ compounds or by changing pH for the ionic compounds. The Mag-PCMAs perform well with a wide range of different organic contaminants with different solubility and $pK_a$. It is expected that the Mag-PCMAs will have potentially wide application in the removal of emerging organic contaminants from water.
