Abstract The R&D activity performed during the last years proved the potential of ZnSe scintillating bolometers to the search for neutrino-less double beta decay, motivating the realization of the first large-mass experiment based on this technology: CUPID-0. The isotopic enrichment in $^{82}$Se crystals growth, as well as the light detectors production have been accomplished, and the experiment is now in construction at Laboratori Nazionali del Gran Sasso (Italy). In this paper we present the results obtained testing the first three Zn$^{82}$Se crystals operated as scintillating bolometers, and we prove that their performance in terms of energy resolution, background rejection capability and intrinsic radio-purity complies with the requirements of CUPID-0.

1 Introduction

Neutrino-less double beta decay (0$\nu$DBD) is a hypothesized nuclear transition in which a nucleus decays emitting only two electrons. This process cannot be accommodated in the Standard Model, as the absence of emitted neutrinos would violate the lepton number conservation. For this reason, its prized observation would have several implications for particle physics, astrophysics and cosmology. According to the majority of theoretical frameworks, for 0$\nu$DBD to happen neutrinos must be Majorana particles. This means that, in contrast to all the other known fermions, they must coincide with their own antiparticles. In this scenario, the half-life of the process $T_{1/2}^{0\nu}$ is determined by the effective Majorana neutrino mass $m_{\beta\beta}$, a linear superposition of the three neutrinos mass eigenstates weighted by the elements of the first row of the PMNS neutrino mixing matrix and including two Majorana phases, providing the dependance: $T_{1/2}^{0\nu} \propto 1/m_{\beta\beta}^2$. 

---

$^a$ e-mail: laura.cardani@roma1.infn.it
Current lower limits on $T^\nu_{1/2}$ exceed $10^{25}$ years for several possible emitters, corresponding to upper bounds on $m_{\beta\beta}$ of a few hundreds of meV [1]. Moreover, recent measurements made by the KamLAND-Zen collaboration using a xenon-loaded liquid scintillator allowed to set a limit on $T^\nu_{1/2}(^{136}\text{Xe})$ of $1.1 \times 10^{26}$ years at 90 % C.L., corresponding to $m_{\beta\beta} < 60$–161 meV [2].

Among the several experimental approaches proposed for the search of $0\nu\text{DBD}$, cryogenic calorimeters [3] (historically also called bolometers) stand out for the possibility of achieving excellent energy resolution (of the order of 0.1 %), efficiency (>80 %) and intrinsic radio-purity. Moreover, the crystals that are operated as bolometers can be grown starting from most of the $0\nu\text{DBD}$ emitters, enabling the test of different nuclei.

The CUORE-0 experiment proved the potential of the bolometric technique by reaching an unprecedented sensitivity on the half-life of $^{130}\text{Te}$ [4]. The $^{130}\text{Te}$ source was embedded in 52 TeO$_2$ bolometers (for a total mass of 39 kg), operated between March 2013 and March 2015 at Laboratori Nazionali del Gran Sasso (LNGS, Italy). The combination of the 9.8 kg($^{130}\text{Te}$)-year exposure collected by CUORE-0 with the 19.75 kg($^{130}\text{Te}$) years of its ancestor, Cudoricino, allowed to set a new limit on the $T^\nu_{1/2}(^{130}\text{Te})$: $T^\nu_{1/2} > 4.0 \times 10^{24}$ years at 90 % C.L., corresponding to $m_{\beta\beta} < 270$–760 meV.

The evolution of CUORE-0, named CUORE [5], will start operation before the end of 2016 with 988 TeO$_2$ bolometers, pointing to a sensitivity of $T^\nu_{1/2}(^{130}\text{Te}) > 9.5 \times 10^{25}$ years at 90 % C.L. ($m_{\beta\beta} < 50$–130 meV). This remarkable sensitivity will allow to touch, but not to fully explore, the $m_{\beta\beta}$ region of 10–50 meV, corresponding to the inverted mass hierarchy of neutrinos (see Refs. [1, 6–8] and references therein for a complete discussion on the relationship between the $0\nu\text{DBD}$ and the neutrino mass hierarchy). The entire coverage of this region, indeed, requires a level of sensitivity of about $10^{27}$–$10^{28}$ years, depending on the isotope [9]. The CUPID (CUORE Upgrade with Particle IDentification [10,11]) interest group is defining the technological upgrades that will allow to reach this target with a CUORE-size bolometric detector. Such an ambitious goal poses a stringent requirement on the background, that must be close to zero at the tonne-year level of exposure.

The experience gained during the years of R&D activity for CUORE allowed to determine that the ultimate limit in the background suppression resides in the presence of $\alpha$-decaying isotopes located in the detector structure. Thus, the main breakthrough of CUPID with respect to CUORE will be the addition of independent devices to measure the light signals emitted either from Cherenkov radiation (in TeO$_2$ [12]) or from scintillation (in scintillating crystals [13] like ZnSe [14,15], ZnMoO$_4$ [16–22], Li$_2$MoO$_4$ [23,24] and many others). The different light emission of electrons and $\alpha$ particles will enable event-by-event rejection of $\alpha$ interactions, suppressing the overall background in the region of interest for $0\nu\text{DBD}$ of at least one order of magnitude. During the last years, several R&D activities demonstrated that the detection of Cherenkov light emitted by electrons crossing the TeO$_2$ crystals of CUORE can provide an effective $\alpha$ background rejection [25]. Despite the encouraging results [26–33], none of these activities is yet mature for a next-generation experiment. A different approach was followed by the LUCIFER [34] and LUMINEU [35] collaborations, that tested different scintillating bolometers and proved that the read-out of the much more intense scintillation light (a few keV or tens of keV depending on the crystal, with respect to ~100 eV produced by Cherenkov radiation) simplifies the suppression of the $\alpha$ background. Moreover, choosing crystals containing high Q-value $0\nu\text{DBD}$ emitters such as $^{82}\text{Se}$ and $^{100}\text{Mo}$ provides a natural suppression of the $\gamma$ background produced by the environmental radioactivity, that drops above the 2615 keV $\gamma$-line of $^{208}\text{Tl}$. The encouraging results obtained with large ZnSe bolometers motivated the endeavor in realizing a first large mass demonstrator of the scintillating bolometers technology: CUPID-0. A second phase of CUPID-0, not described in this paper, will include also enriched $\text{Li}_2^{100}\text{MoO}_4$ and Zn$^{100}\text{MoO}_4$ crystals, which showed excellent performance as scintillating bolometers. CUPID-0 aims at proving that the interactions due to $\alpha$ particles can be efficiently suppressed, providing a path to ensure the achievement of the zero-background level required by CUPID.

2 CUPID-0

The CUPID-0 detector will consist of 30 $^{82}\text{Se}$ bolometers arranged in 5 towers, for a total mass of 13.2 kg (7.0 kg of $^{82}\text{Se}$). The Q-value of $^{82}\text{Se}$ (2997.9 ± 0.3 keV [36]) is among the highest, and the half-life of the $2\nu\beta\beta$ mode is long enough ($T^\nu_{2\nu}=(9.6 \pm 0.1(\text{stat}) \pm 1.0(\text{syst})) \times 10^{20}$ years [37]) to prevent $2\nu\beta\beta$ background contributions in the region of interest. To date, all the crystals (Zn$^{82}\text{Se}$ and Ge light detectors) were grown and delivered to LNGS. The assembly of the CUPID-0 is expected to be completed before the end of Summer 2016.

The Se powder was enriched at URENCO Stable Isotope Group (Netherlands) to overcome the rather poor natural isotopic abundance of $^{82}\text{Se}$ (8.73 % [38]). We measured the radio-purity of the 96.3 % enriched powder with HP-Ge spectroscopy and, since we found no evidences of contaminations, we set upper limits of 61, 110 and 74 Bq/kg at 90 % C.L. for $^{232}\text{Th}$, $^{238}\text{U}$ and $^{235}\text{U}$, respectively [39]. We measured with the same sensitivity also Zn metal, and found no signatures of $^{232}\text{Th}$, $^{238}\text{U}$ and $^{235}\text{U}$. 
The Zn$^{82}$Se synthesis, as well as the crystals growth were performed at the Institute for Scintillation Materials (ISMA, Kharkov, Ukraine). To prevent contaminations, the synthesis and the subsequent powder purification treatments were performed in Argon atmosphere using tools/containers selected according to their radio-purity. After the test run described in this paper, all the 95.4 % enriched CUPID-0 crystals were cut, shaped and polished in order to obtain bolometers with 4.4 cm diameter and 5.5 cm height, for an average mass of 440.5 g. These operations were carried out in a clean room at LNGS following the protocols for radio-purity described in Ref. [40]. The procedures that we developed for the Zn$^{82}$Se synthesis and purification allowed to reach a yield of 98 %, with 2 % irrecoverable loss of enriched Se. The yield of the crystals production was reduced by losses of material evaporated during the crystal growth. The crystals presented in this paper were grown using graphite crucible, with an irrecoverable loss of material of about 15 %. The growth procedure was then optimized in order to reduce the material loss down to 2 % using glassy graphite crucible. The fraction of material discarded during the manufacturing process (about 40 %) can be reprocessed to obtain other Zn$^{82}$Se crystals. More details about the synthesis, crystal growth and processing can be found in Ref. [41].

The scintillation light emitted by each Zn$^{82}$Se will be measured by two light detectors [42], facing the top and bottom surfaces of the crystal (see Fig. 1a). The light detectors are also bolometers made of disk-shaped Ge crystals (4.4 cm diameter) grown by UMICORE using the Czochralski technique. Since the energy emitted as scintillation light is only a few % of the total, the Ge crystals must be very thin to ensure a low heat capacity and, thus, a higher signal. For this reason, the light detectors were cut in 170$\mu$m thick wafers, that were polished and etched on both sides. The face showing the best optical properties was coated with a thin layer (70 nm) of SiO in order to increase the light absorption [43,44].

To convert temperature variations into readable voltage signals, each ZnSe and Ge crystal will be equipped with a Neutron Transmutation Doped (NTD) Ge thermistor using a semi-automatic gluing system. In addition, a Si Joule heater will be glued to the crystals for the offline correction of thermal drifts by heat pulses injection [45].

The Zn$^{82}$Se and Ge bolometers will be mounted in an Oxygen Free High Conductivity (OFHC) copper structure, serving as thermal bath to cool the detectors at $\sim$10 mK. To account for different thermal contractions of the detectors and copper, the crystals will be secured to the copper frames using PTFE elements, acting also as weak thermal coupling to the bath. The final layout of the CUPID-0 detector, that will be hosted in the same cryostat used for CUORE-0 with an upgrade for the reduction of the microphonic noise, is shown in Fig. 1.

To test the CUPID-0 assembly line, as well as to verify the compliance of the final detectors with the requirements on energy resolution, background rejection capability and intrinsic radio-purity, we mounted an array of three Zn$^{82}$Se crystals and performed a bolometric run. In this paper we present the results of the test run and discuss the perspectives for CUPID-0.

### 3 Detector

The detector consists of three Zn$^{82}$Se crystals (for a total Zn$^{82}$Se mass of about 1.32 kg) and four light detectors, arranged in a single tower following the layout depicted in Fig. 1.

Apart from the number of crystals, there are only few differences with the final CUPID-0 protocol for the detector assembly: (1) the cleaning procedure defined for the surface of the crystals in CUPID-0 was not yet applied to the present crystals, as we were interested mainly in the bolometric performance and crystal bulk contaminations, (2) the detector was mounted above-ground, shortly after the crystal growth, while the CUPID-0 towers will be assembled in a Radon-free underground clean room using crystals stored underground to reduce the cosmogenic activation, (3) during the measurement the Zn$^{82}$Se were permanently exposed to smeared $\alpha$ sources of $^{147}$Sm (Q-value $\sim$2.3 MeV) to assess the background rejection capability in a short measurement time.

We used two classes of NTD Ge thermistors, characterized by different dimensions: the large sensors (2.8 $\times$ 3.0 $\times$ 1.0 mm) were attached on Zn$^{82}$Se bolometers, while the smaller ones...
Fig. 2 Two stages of the tower assembly. Left a light detector equipped with an NTD Ge thermistor and a Si Joule heater is mounted on top of a Zn$^{82}$Se bolometer, surrounded by a 3M VM2002 reflecting foil. Right the second Zn$^{82}$Se bolometer is placed on top of the previous light detector

(2.8×2.0×0.5 mm) were glued to the light detectors that, because of their much smaller mass, require sensors with lower heat capacity. Two stages of the detector assembly are shown in Fig. 2.

The Zn$^{82}$Se array was anchored to the coldest point of a $^3$He/$^4$He dilution refrigerator located in the Hall C of LNGS. For technical reasons, the refrigerator could not be operated below 20 mK, which is however satisfactory for our purposes. The final CUPID-0 towers will reach a much lower base temperature (about 10 mK) exploiting the cryostat that was used for the CUORE-0 experiment.

The signals were amplified by high gain voltage amplifiers with input stages based on Silicon JFETs, filtered by a 6-pole low-pass Bessel–Thomson filter [46–48] with roll-off rate of 120 dB/decade, and fed into an 18 bit NI-6284 PXI ADC unit. Due to the different time development of heat and light pulses (shown in Fig. 3) we set a cut-off frequency of 63 Hz for Zn$^{82}$Se and 200 Hz for light detectors. When the software trigger of each Zn$^{82}$Se fired, we saved on disk 5 s long time-windows sampled at 1 kHz. The light detectors were acquired with a shorter window of 250 ms and a higher sampling frequency (2 kHz).

In addition to the derivative trigger, we used a second trigger that forced the acquisition of the light detectors every time the trigger of a Zn$^{82}$Se fired.

To maximize the signal-to-noise ratio, the waveforms were processed offline with the optimum filter algorithm [49, 50]. Unlike the classical nuclear pulse shape processing (gaussian, semi-gaussian, CR-(RC)$^n$ etc.) the optimum filter estimates the signal at each frequency with weights equal the signal-to-noise ratio at the same frequency, embedding in its shape the proper timing parameters. In our case it behaves as a pass-band filter with the lower frequency optimized for 1/f noise rejection, while the higher frequency is limited by signal roll-off, minimizing the contribution of white noise. Since light pulses feature a worse signal-to-noise ratio, we used a dedicated algorithm, exploiting the known time-delay between heat and light signals, to compute their amplitude [51].

The general features of the Zn$^{82}$Se bolometers are reported in Table 1. The working resistance of the NTD Ge thermistor $R_{\text{work}}$ depends on the detector temperature: the lower the temperature, the larger the resistance. The electronics channels are optimized for $R_{\text{work}}$ of the order of tens/hundreds of MΩ (corresponding to a crystal temperature lower than 10 mK) but the high base temperature of the cryostat prevented the achievement of such a resistance, somehow spoiling the detector performance. Given the low values of $R_{\text{work}}$ (reported in Table 1), we estimated a noise contribution from the electronics of 7.0 keV FWHM for Zn$^{82}$Se-1, 14.3 keV for Zn$^{82}$Se-2 and 18.3 keV for Zn$^{82}$Se-3. These values are in full agreement with the measured energy resolution of the detector baseline (Table 1), leading to the consideration that a lower cryostat temperature would have provided a much better baseline resolution, as observed in other ZnSe prototypes [15]. The analysis of the noise power spectra of the detectors allowed to infer that the degradation of the baseline resolution could be mainly ascribed to the series noise (both 1/f and white) of the very front-end system, operated in unmatched conditions. Nevertheless, our primary interest was the study of the detector performance at high energy where, as shown in the next section, the electronics noise is negligible. Furthermore, also the response of the bolometer, defined as the voltage signal produced by an energy deposit of 1 MeV, was affected by the higher than usual detector temperature. A lower temperature of operation, to be expected in the next runs, will allow to increase the energy conversion
Table 1: Resistance of the NTD Ge thermistor in working conditions

| Resistance of the NTD Ge thermistor in working conditions $R_{\text{work}}$, FWHM noise energy resolution after the optimum filter, voltage signal (in $\mu$V) produced by an energy release of 1 MeV |
|-----------------|-----------------|-----------------|
| $Zn^{82}\text{Se-1}$ | 0.20 $\Omega$ | 7.0 keV FWHM | 7.1 $\mu$V/MeV |
| $Zn^{82}\text{Se-2}$ | 0.22 $\Omega$ | 14.1 keV FWHM | 3.7 $\mu$V/MeV |
| $Zn^{82}\text{Se-3}$ | 0.17 $\Omega$ | 18.6 keV FWHM | 2.9 $\mu$V/MeV |

4 Energy resolution

The $Zn^{82}\text{Se}$ bolometers were energy calibrated using $^{228}\text{Th}$ and $^{40}\text{K}$ sources, emitting $\gamma$ rays up to 2615 keV. We fitted the most intense $\gamma$ peaks to check the linearity of the detector response, as well as to determine the energy resolution (see Fig. 4 for $Zn^{82}\text{Se-1}$).

Since the $\gamma$ natural radioactivity drops above the 2615 keV line, we could not rely on calibration peaks at the Q-value of $^{82}\text{Se}$. For this reason, we estimated the energy resolution in the ROI by fitting the energy resolution of the calibration peaks as a function of the energy with the following function:

$$FWHM^2(E) = FWHM_{\text{baseline}}^2 + \alpha E^\beta$$

where $FWHM_{\text{baseline}}^2$ accounts for the contribution of the electronic noise (see Table 1), and $\alpha$ and $\beta$ are arbitrary coefficients. At the $^{82}\text{Se}$ Q-value we derived a FWHM energy resolution of $30.1 \pm 1.7$ keV ($Zn^{82}\text{Se-1}$), $29.7 \pm 1.4$ keV ($Zn^{82}\text{Se-2}$) and $30.2 \pm 1.7$ keV ($Zn^{82}\text{Se-3}$), proving the reproducibility of the $Zn^{82}\text{Se}$ bolometers.

These values are about a factor 3 larger than the initial target of the experiment (10 keV FWHM [34]). Even if a further cooling of the crystals is expected to improve the resolution, we will demonstrate in the next sections that $Zn^{82}\text{Se}$ bolometers with 30 keV FWHM would anyway comply with the requirements of CUPID-0.

5 Performance of light detectors

The sensitivity of light detectors is crucial for CUPID-0, as the background rejection capability relies on the different light emission of electrons and $\alpha$ particles. In this run, all the light detectors were permanently exposed to $^{55}\text{Fe}$ X-rays sources (characterized by peaks at 5.9 and 6.4 keV) for energy-calibration. To further investigate the reproducibility of light detectors, we assembled a second array, with three $Zn^{nat}\text{Se}$ interleaved by four Ge disks. Two of these light detectors were equipped with large NTD Ge thermistors, similar to those attached on $Zn^{nat}\text{Se}$ crystals, to investigate the effect of the sensor heat capacity on the bolometric performance. The features of the light detectors are reported in Table 2.

As explained in Sect. 3, the high cryostat temperature could produce an electronic noise limiting the detector energy resolution. Nevertheless, it is worth highlighting that, in absence of any signal amplification, energy resolutions as good as those reported in Table 2 have never been achieved with wide area Ge light detectors equipped with conventional NTD Ge thermistors. The detector response in terms of signal height, as well as the energy resolution, showed variations lower than 40% across the 6 light detectors equipped with small NTD Ge sensors, proving the reproducibility of the light detectors performance in view of CUPID-0. These results can mainly be ascribed to the improvement of the interface between the Ge disks and the NTD Ge thermistors provided by dedicated surface treatments (etching and polishing), as well as by the semi-automatic gluing system that enhanced the reproducibility of the detectors features.

6 Background study

6.1 Cosmogenic activation

To investigate the cosmogenic activation of $Zn^{82}\text{Se}$ crystals we exploited the comparison between data extracted from the
cosmogenic activation calculation software Activia [52] and the measurements performed with this array. The isotope of (enriched) Selenium with the highest activation rate is $^{75}$Se (Q-value $\sim 864$ keV, $T_{1/2} \sim 118$ d) which decays via electron capture with a rather complex combination of de-excitation $\gamma$’s and X-rays. None of the enriched crystals showed evidences of $^{75}$Se, and we set a 90% C.L. upper limit on its activity of 14 $\mu$Bq/kg. All the other isotopes are expected to have a much lower activation rate. Among them, the only emitters that could produce background events for the $0^\nu \alpha$ much lower activation rate is $^{65}$Zn (Q-value $\sim 3.06 \pm 0.44$ MeV). All these isotopes are expected to have activation rates about 3 orders of magnitude lower than $^{75}$Se. Furthermore, due to their short half-lives, they will not participate to the background of CUPID-0, as the crystals will be permanently stored underground until operations.

We performed a similar analysis to investigate the activation of Zn. In this case, the isotope with highest activation rate is $^{65}$Zn (Q-value $\sim 1352$ keV and $T_{1/2} \sim 244.26$ d). The signature of $^{65}$Zn was observed in all the Zn$^{82}$Se crystals with similar activities of 3.06±0.44 mBq/kg. Also in this case, $^{48}$V and $^{56}$Co would be the only dangerous emitters produced by cosmogenic activations, with activation rates much lower than $^{65}$Zn. As said before, due to the low activation and the short half-lives, these isotopes will not be of concern for CUPID-0.

Nevertheless, since this test run was performed shortly after the crystal production and delivery, we expect $^{56}$Co to contribute about 1 $\gamma$/day in the total energy spectrum of the array above 2615 keV.

6.2 Alpha background rejection

The large light output of Zn$^{82}$Se crystals and the excellent performance of the cryogenic light detectors provided a very efficient $\alpha$ background rejection. The three crystals featured a similar light yield (LY), defined as the amount of light (in keV) measured when an interaction of 1 MeV occurs in the Zn$^{82}$Se bolometer. ZnSe crystals operated at cryogenic temperatures show a rather peculiar (and not yet fully understood) feature: the LY of electrons is lower with respect to the one of $\alpha$ particles. With this array we measured LY$\beta/\gamma$ ranging from 3.3 to 5.2 keV/MeV, to be compared with LY$\alpha$ ranging from 9.1 to 14.1 keV/MeV.

Even if the different LY allows to identify and separate electrons and $\alpha$ events, we used a more powerful estimator for background rejection: the shape of the light pulses. As shown in the inset of Fig. 5, the light pulses produced by $\beta/\gamma$ interactions are slower than light pulses produced by $\alpha$’s of the same energy.

To exploit this difference, we used a shape-sensitive parameter (SP) computed on the optimum filtered pulse and defined as:

$$SP = \frac{1}{A_{w_f}} \sqrt{\frac{1}{i_M + w_y} \sum_{i = i_M}^{i_M + w_y} (y_i - A s_i)^2}$$

where $y_i$ is the pulse, A and $i_M$ its amplitude and maximum position, $s_i$ the ideal signal pulse scaled to unitary amplitude and aligned to $y_i$, $w_f$ the right width at half maximum of $s_i$. The Shape Parameter of light pulses computed for the best light detector is shown for Zn$^{82}$Se-1 in Fig. 5.

Because of the worse signal-to-noise ratio, the $\beta/\gamma$ and $\alpha$ bands become wider at lower energies. To compute the discrimination capability at the $0\nu$DBD energy, we divided

Table 2 Features of light detectors equipped with small NTD Ge sensors: $\tau_r$ and $\tau_d$ are the rise and decay times, computed as the time difference between the 90 and 10% of the leading edge and as the time difference between the 30 and 90% of the trailing edge respectively. The other parameters were defined in Table 1. In the last two lines we report the features of light detectors equipped with large NTD Ge sensors.

"cosmogenic activation calculation software Activia [52] and the measurements performed with this array. The isotope of (enriched) Selenium with the highest activation rate is $^{75}$Se (Q-value $\sim 864$ keV, $T_{1/2} \sim 118$ d) which decays via electron capture with a rather complex combination of de-excitation $\gamma$’s and X-rays. None of the enriched crystals showed evidences of $^{75}$Se, and we set a 90% C.L. upper limit on its activity of 14 $\mu$Bq/kg. All the other isotopes are expected to have a much lower activation rate. Among them, the only emitters that could produce background events for the $0^\nu \alpha$ much lower activation rate is $^{65}$Zn (Q-value $\sim 3.06 \pm 0.44$ MeV). All these isotopes are expected to have activation rates about 3 orders of magnitude lower than $^{75}$Se. Furthermore, due to their short half-lives, they will not participate to the background of CUPID-0, as the crystals will be permanently stored underground until operations.

We performed a similar analysis to investigate the activation of Zn. In this case, the isotope with highest activation rate is $^{65}$Zn (Q-value $\sim 1352$ keV and $T_{1/2} \sim 244.26$ d). The signature of $^{65}$Zn was observed in all the Zn$^{82}$Se crystals with similar activities of 3.06±0.44 mBq/kg. Also in this case, $^{48}$V and $^{56}$Co would be the only dangerous emitters produced by cosmogenic activations, with activation rates much lower than $^{65}$Zn. As said before, due to the low activation and the short half-lives, these isotopes will not be of concern for CUPID-0.

Nevertheless, since this test run was performed shortly after the crystal production and delivery, we expect $^{56}$Co to contribute about 1 $\gamma$/day in the total energy spectrum of the array above 2615 keV.

6.2 Alpha background rejection

The large light output of Zn$^{82}$Se crystals and the excellent performance of the cryogenic light detectors provided a very efficient $\alpha$ background rejection. The three crystals featured a similar light yield (LY), defined as the amount of light (in keV) measured when an interaction of 1 MeV occurs in the Zn$^{82}$Se bolometer. ZnSe crystals operated at cryogenic temperatures show a rather peculiar (and not yet fully understood) feature: the LY of electrons is lower with respect to the one of $\alpha$ particles. With this array we measured LY$\beta/\gamma$ ranging from 3.3 to 5.2 keV/MeV, to be compared with LY$\alpha$ ranging from 9.1 to 14.1 keV/MeV.

Even if the different LY allows to identify and separate electrons and $\alpha$ events, we used a more powerful estimator for background rejection: the shape of the light pulses. As shown in the inset of Fig. 5, the light pulses produced by $\beta/\gamma$ interactions are slower than light pulses produced by $\alpha$’s of the same energy.

To exploit this difference, we used a shape-sensitive parameter (SP) computed on the optimum filtered pulse and defined as:

$$SP = \frac{1}{A_{w_f}} \sqrt{\frac{1}{i_M + w_y} \sum_{i = i_M}^{i_M + w_y} (y_i - A s_i)^2}$$

where $y_i$ is the pulse, A and $i_M$ its amplitude and maximum position, $s_i$ the ideal signal pulse scaled to unitary amplitude and aligned to $y_i$, $w_f$ the right width at half maximum of $s_i$. The Shape Parameter of light pulses computed for the best light detector is shown for Zn$^{82}$Se-1 in Fig. 5.

Because of the worse signal-to-noise ratio, the $\beta/\gamma$ and $\alpha$ bands become wider at lower energies. To compute the discrimination capability at the $0\nu$DBD energy, we divided
the $\alpha$ and $\beta/\gamma$ bands in intervals and made Gaussian fits to derive the mean value ($\mu$) and the standard deviation ($\sigma$) of the Shape Parameter in each interval. We fitted the energy dependence of $\mu(E)$ and $\sigma(E)$ with polynomial functions and defined the Discrimination Power (DP) as a function of the energy as:

$$DP(E) = \frac{|\mu_\alpha(E) - \mu_\beta(E)|}{\sqrt{\sigma_\alpha^2(E) + \sigma_\beta^2(E)}}$$

and found $DP = 12$ at the $^{82}$Se Q-value. The same analysis was made on the other two crystals, obtaining a DP of 11 and 10 for Zn$^{82}$Se-2 and Zn$^{82}$Se-3 respectively.

We report in Fig. 6 the zoom at high energy of the spectrum collected with the Zn$^{82}$Se array in about 530 h, before and after the rejection of the $\alpha$ background and of the events occurring simultaneously in more than one crystal.

The number of events above the $^{208}$Tl peak is very small if we consider that the cryogenic set-up used for this test did not provide an efficient shield against $^{214}$Bi produced in Rn-contaminated air, and that the crystals were measured immediately after production (when the activation could still give rise to an important background). For CUPID-0 we foresee an even better result, as the cryostat used by CUORE-0 will be equipped with a more effective Rn-free system and a more efficient shielding. Moreover, storing the crystals underground will suppress the activity of isotopes like $^{56}$Co ($T_{1/2} \sim 79$ d) that, as explained in the previous section, was expected to produce a non-negligible background in this run.

6.3 Crystal contaminations

The radio-purity of Zn$^{82}$Se crystals is of primary concern for the achievement of the target sensitivity, as the long-living isotopes of the natural $^{238}$U and $^{232}$Th chains may give rise to an irreducible background in the region of interest around 3 MeV.

Due to their very short range, $\alpha$ particles can give a clear indication of bulk or surface contaminations. If the $\alpha$-decaying isotope is located in the crystal bulk, both the $\alpha$ particle and the nuclear recoil are absorbed by the bolometer, giving rise to a peak at the Q-value of the decay. On the contrary, if the contaminant is located on the crystal surface, $\alpha$’s (and with much lower probability nuclear recoils) may leave the crystal before being stopped and the event is recorded with an energy lower than the Q-value. Only for very shallow surface contamination the $\alpha$ line (about 100 keV below the Q-value) becomes visible.

To extract the crystal contaminations in the isotopes of the $^{238}$U and $^{232}$Th chains, we analyzed the $\alpha$ region of the total energy spectrum, reported in Fig. 7. The same analysis was performed on the energy spectra of each Zn$^{82}$Se to highlight possible differences, and the results are shown in Table 3. In some cases we had no evidences of contaminations, thus we reported the 90 % C.L. upper limit. For this purpose, we defined the signal as the number of events falling in the energy interval $[Q-value - 3\sigma, Q-value + 3\sigma]$ and the background as the average number of events falling in the $3\sigma$ side-bands of this interval. Following the Feldman–Cousins approach, we computed the 90 % C.L. upper limit on the number of events and, correcting for the branching ratio of the nuclide, we inferred the upper limit on the activity. The $\alpha$ lines not quoted in the table are the two $\sim 6$ MeV lines of $^{232}$Th because they produce a pile-up event rejected as a deformed signal by pulse shape cuts, and the two $\alpha$ lines that in both chains are summed to the following beta emission (Bi-Po events) producing a continuum above 8 MeV.
Table 3 Crystal contaminations in the isotopes of $^{238}$U and $^{232}$Th chains derived from the analysis of the $\alpha$ region (see Fig. 7). We made the same analysis on the energy spectrum of each Zn$^{32}$Se bolometer to highlight differences among crystals. Isotopes with long half-lives, that can break the secular equilibrium, are highlighted in bold type

The energy spectrum reported in Fig. 7 was reconstructed using a Monte Carlo simulation (not shown), obtaining activities compatible with those reported in Table 3.

The position and shape of the $\alpha$ peaks suggested that most of the contaminations are uniformly diffused in the crystal bulk, but we could not completely exclude the hypothesis that part of the contaminations is located deep in the crystal surface. For simplicity, however, the activities reported in Table 3 were normalized to the mass of the crystals.

The only isotope showing a clear evidence for a surface contamination was $^{210}$Po that, because of its rather short half-life ($\sim$138 days) was likely produced by $^{210}$Pb. As shown in Fig. 7, $^{210}$Pb produced two structures at $\sim$5.3 MeV ($\alpha$) and $\sim$5.4 MeV ($\alpha$ + nuclear recoil). The presence of the first peak could be explained by the simulation only assuming a shallow contamination of the crystal surface or of the inert materials surrounding the detector. The activity of $^{210}$Pb shown in Table 3 was computed attributing the entire event rate (surface + bulk) to a contamination of the crystal bulk. The presence of this contaminant, however, is not of concern for CUPID-0, as none of the daughters of $^{210}$Pb/$^{210}$Po produces $\beta/\gamma$ events.

In contrast to $^{210}$Po, the signature of isotopes belonging to $^{238}$U and $^{232}$Th chains could be explained both by crystal bulk contaminations, and by deep contaminations of the crystal surface (> 0.1µm). If the contaminations were located in the crystal surface, we would expect a background reduction after the surface processing. The Zn$^{32}$Se crystals, indeed, will be treated with a cleaning procedure similar to the one developed for TeO$_2$ crystals by the CUORE collaboration [40], that proved to be very effective.

Finally, the GEANT-4 simulation allowed to infer the expected background contribution to the region of interest for CUPID-0. We implemented the geometry described in Fig. 1, and assumed a discrimination power of 12 (see Sect. 6.2), and an energy resolution of 30 keV at the Q-value of $^{82}$Se (see Sect. 4).

If all the contaminations were diffused in the crystal bulk, we would expect a background at the $^{82}$Se Q-value of $4 \times 10^{-2}$ counts/keV/kg/year. Since 0νDBD electrons are expected to be contained in a single crystal (with a containment efficiency of 80%), while the events produced by $^{208}$Tl decay mainly occur in more than one detector, we can exploit coincidences among nearby crystals to suppress this background to the level of 2.3 × 10$^{-2}$ counts/keV/kg/year. Taking advantage of the small time delay between $^{208}$Tl and its mother ($^{212}$Bi), we can reach a level of 1 × 10$^{-3}$ counts/keV/kg/year with a negligible dead-time (2%) [15,19], in compliance with the requirements of CUPID-0.

If all the contaminations were located only on the crystal surface, and in the unlikely event that crystal polishing does not change crystal surface activity, the background in the region of interest would be of 6 × 10$^{-3}$ counts/keV/kg/year (coincidence suppression included), dominated by $^{208}$Tl interactions. In this case, the background suppression obtained exploiting the time delay between $^{208}$Tl and $^{212}$Bi would be slightly less effective, and would allow to reach the level of 3 × 10$^{-3}$ counts/keV/kg/year. However, following what observed in CUORE [53,54], crystal surface treatment allows a reduction of surface activity by more than a factor 6. In this case the expected counting rate could be even lower than 10$^{-3}$ counts/keV/kg/year.

7 Conclusions and perspectives

The results presented in this paper allowed to assess the performance of the first Zn$^{32}$Se array in view of CUPID-0. We demonstrated that the assembly line guarantees the reproducibility both of light detectors, characterized by an unprecedented sensitivity, and of Zn$^{32}$Se bolometers. We derived the energy resolution of Zn$^{32}$Se detectors, obtaining 30 keV FWHM at the Q-value of $^{82}$Se 0νDBD, and we proved that the excellent performance of light detectors allows to completely disentangle and reject the background due to $\alpha$ interactions.

CUPID-0 is expected to run at least for 1 y of live-time to prove the potential of the scintillating bolometers technology, and the high number of emitters will allow to reach a remarkable sensitivity on the $^{82}$Se 0νDBD. Thanks to the low crystal contaminations, the expected background should be lower than 1.5 × 10$^{-3}$ counts/keV/kg/year, mainly produced by the cryogenic setup [34]. As explained in Ref [55], when the background is low enough to produce a number of events in the ROI of the order of unity along the experiment life (“zero background” approximation), the sensitivity scales as:
\[ S_{1/2}^{\text{no}} = -\frac{ln(2)}{ln(1-C.L./100)} \frac{N_{\text{Ann}}}{W} \epsilon \cdot M \cdot t \cdot f(\delta E) \]

where C.L. is the confidence level, \( N_A \) the Avogadro constant, \( a \) the isotopic abundance, \( \eta \) the stoichiometric coefficient of the \( 0\nu\beta\beta \) candidate, \( W \) the atomic weight. \( \epsilon \) is the efficiency (80\% for these \( ^{82}\text{Se} \), \( M \) the detector active mass, \( t \) the live-time and \( f(\delta E) \) the fraction of signal event that fall into the considered energy region (0.76 when \( \delta E \) is the detector FWHM energy resolution).

Given a background index of \( 1.5 \times 10^{-3} \) counts/keV/kg/year, we expect \( \sim 0.6 \) events in 1 year in a FWHM energy interval centered around the \( ^{82}\text{Se} \) Q-value. With a lower cryostat temperature, we expect CUPID-0 to feature a better energy resolution and, as a consequence, an even lower number of background events in the region of interest. Thus, the sensitivity can be computed in the “zero background” approximation and results 9.3 \( \times 10^{-4} \) at 90\% C.L. in 1 year of data taking. The sensitivity will increase linearly with the live-time of the experiment as long as the conditions will be compatible with the zero background approach.

Acknowledgments This work was partially supported by the LUCIFER experiment, funded by ERC under the European Union’s Seventh Framework Programme (FP7/2007-2013)/ERC grant agreement n. 247115, funded within the ASPERA 2nd Common Call for R&D Activities. We are particularly grateful to M. Iannone for its help in all the stages of the detector construction, to M. Guetti for the assistance in the cryogenic operations and to the mechanical workshop of LNGS (in particular E. Tatananni, A. Rotilio, A. Corsi, and B. Romualdi) for continuous and constructive help in the overall set-up design.
