Abstract

A detailed account is given of observations of parity nonconservation in the $^2P_{1/2} - ^2P_{1/2}$ transition in $^{203,205}$TI. Absorption of circularly polarized 293 nm photons by $^2P_{1/2}$ atoms in an E field results in polarization of the $^2P_{1/2}$ state through interference of the Stark E1 amplitude with M1 and parity nonconserving E1 amplitudes. This polarization is detected by selective excitation of $m_F = \pm 1$ components of $^2P_{1/2}$ state to the $^2S_{1/2}$ state and observation of the ensuing decay fluorescence at 323 nm. Systematic corrections due to imperfect circular polarization, misaligned E fields, and residual magnetic fields are determined precisely by a series of auxiliary experiments. The result is expressed in terms of the circular dichroism $\delta_{\text{expt}} = +(2.8 \pm 1.0) \times 10^{-3}$, to be compared with theoretical estimates based on the Weinberg-Salam model for $\sin^2 \theta_W = 0.23$: $\delta_{\text{theo}} = +(2.1 \pm 0.7) \times 10^{-3}$. 
1. Introduction

In this paper we report observations of parity nonconservation in the $2^2p_{1/2} - 7^2p_{1/2}$ transition in atomic thallium ($Z = 81, A = 203, 205$). This effect occurs because of the neutral weak interaction between valence electron and nucleus, and its observation provides a useful test of the Weinberg-Salam (standard) model of weak and electromagnetic interactions. Parity nonconservation in the electron-nucleon interaction has also been observed in scattering of high energy polarized electrons on deuterium and in optical rotation experiments in atomic bismuth.

The results of a preliminary version of the present experiment, and more recently a brief summary of our latest results, have already been published. Here we present a detailed description of the experimental apparatus and procedure, an analysis of systematic errors and corrections, a summary of results and a comparison with theory and other experiments.

It is generally assumed that the neutral weak interaction between electron (e) and nucleon (N) occurs by exchange of a massive neutral vector boson $Z^0$. This exchange modifies the Coulomb hamiltonian by adding an effective zero-range potential $H'$ containing scalar ($S$) and pseudoscalar ($P$) parts: $H' = H_S + H_P$. Assuming the standard model, the dominant contribution to $H_P$ is:

$$H_W = \frac{G}{2\sqrt{2}} Q_W \rho(\vec{r}) \gamma_5$$

where $G$ is the Fermi coupling constant, $Q_W = (1 - 4 \sin^2 \theta) Z - N$ and $\rho(\vec{r})$ is the nuclear density, $\vec{r}$ being the electron position. Matrix elements of $H_W$ are non-zero only for atomic orbitals of opposite parity.
with non-vanishing value or gradient at the nucleus \((s_{1/2}, p_{1/2}\) orbitals), and these matrix elements vary approximately as \(z^3\).

The transition \(6^2P_{1/2} \rightarrow 7^2P_{1/2}\) in Tl (see Fig. 1) is forbidden with measured amplitude \[^{15} M = (-2.1 \pm 0.3) \times 10^{-5} \frac{eh}{2mc}\]

Parity nonconservation causes the \(6^2P_{1/2}, 7^2P_{1/2}\) states to be admixed with \(2s_{1/2}\) states and the transition amplitude acquires an electric dipole component \(\mathcal{E}_p\), given to order \(G\) by:

\[
\mathcal{E}_p = \sum_{n^2S_{1/2}} \left[ \frac{\langle 7^2P_{1/2} | \mathcal{O}_{EM} | nS \rangle \langle nS | H_W | 6^2P_{1/2} \rangle}{E_{6P_{1/2}} - E_{nS}} + \frac{\langle 7^2P_{1/2} | H_W | nS \rangle \langle nS | \mathcal{O}_{EM} | 6^2P_{1/2} \rangle}{E_{7P_{1/2}} - E_{nS}} \right] 
\]

where \(\mathcal{O}_{EM}\) is the electromagnetic transition operator. Interference between \(\mathcal{E}_p\) and \(M\) results in circular dichroism, defined by:

\[
\delta = \frac{\sigma^+ - \sigma^-}{\sigma^+ + \sigma^-} = \frac{2 \text{Im}(M\mathcal{E}_p)}{\left| M \right|^2 + \left| \mathcal{E}_p \right|^2} \approx \frac{2 \text{Im} \mathcal{E}_p}{\left| M \right|^2} \]

where \(\sigma^\pm\) are the cross sections for resonant absorption of 293 nm circularly polarized photons with \(\pm\) helicity respectively. (Time reversal invariance requires \(\mathcal{E}_p\) and \(M\) to be relatively imaginary.) Theoretical estimates of \(\mathcal{E}_p\) and \(\delta\) have been carried out by a number of authors \(^{5,16,17}\). The wave functions generated in some of these calculations \(^{17}\) have been used to compute various auxiliary quantities for comparison with spectroscopic data. In general, agreement between calculation and experiment for these quantities is very satisfactory. For \(\sin^2 \theta_W = 0.23\) one obtains:
\[ \delta_{\text{theo}} = \frac{2 \text{Im}(\delta_p, \text{theo})}{M_{\text{expt}}} = + (2.1 \pm 0.7) \times 10^{-3} \] (5)

Recently, more sophisticated many-body calculations of \( \delta_p \) have been carried out, yielding a similar result\(^\text{18}\).

2. Experimental Method

We employ a method first suggested by Bouchiat and Bouchiat\(^\text{4}\), in which an external electric field \( E \) is applied to Tl vapor. This field Stark-mixes \( ^2P_{1/2} \) states with \( ^2S_{1/2} \) and \( ^2D_{3/2} \) states. The \( ^6P_{1/2} - ^7P_{1/2} \) transition intensity, proportional to \( E^2 \), is thus increased above background (the latter being due to light scattering and atom-atom collisions). Interference between \( M \) and the Stark amplitude, and between \( \delta_p \) and the Stark amplitude, results in a polarization of the \( ^7P_{1/2} \) state. Let the 293 nm (uv) photon beam be along \( \hat{x} \) and choose \( \delta_p = E \hat{y} \) (See Fig. 2a). One then finds the \( ^7P_{1/2} \) polarization along \( \hat{z} \) to be:

\[ P_z (F = 0 \rightarrow F' = 1) = - \frac{2M}{\beta E} (1 \pm \delta/2) \] (6)

\[ P_z (F = 1 \rightarrow F' = 1) = \frac{(4\alpha - 2\beta)M}{(3\alpha^2 + 2\beta^2)E} (1 \pm \delta/2) \] (7)

\[ P_z (F = 0 \rightarrow F' = 0) = 0 \] (8)

for each indicated hfs component \( ^6P_{1/2}, F \rightarrow ^7P_{1/2}, F' \) of the transition\(^\text{19}\).

Here \( \pm \) refer to \( \pm 293 \) nm photon helicities. Also \( \alpha E, \beta E \) are Stark amplitudes, with:
\[
\begin{align*}
\alpha &= \frac{1}{9} \sum_{nS} R_{7P,nS} R_{6P,nS} \left( \frac{1}{E_7 - E_{nS}} + \frac{1}{E_6 - E_{nS}} \right) \\
&\quad + \frac{2}{9} \sum_{nD,3/2} R_{7P,nD} R_{6P,nD} \left( \frac{1}{E_7 - E_{nD}} + \frac{1}{E_6 - E_{nD}} \right) \\
\beta &= \frac{1}{9} \sum_{nS} R_{7P,nS} R_{6P,nS} \left( \frac{1}{E_6 - E_{nS}} - \frac{1}{E_7 - E_{nS}} \right) \\
&\quad + \frac{1}{9} \sum_{nD,3/2} R_{7P,nD} R_{6P,nD} \left( \frac{1}{E_7 - E_{nD}} - \frac{1}{E_6 - E_{nD}} \right)
\end{align*}
\]

where \( E_6 = E(6^{2}P_{1/2}) \), \( E_7 = E(7^{2}P_{1/2}) \), and \( R_{7P,nS} = \langle 7^{2}P_{1/2} | r | n^{2}S_{1/2} \rangle \), etc.

The parity nonconserving terms in the polarization (i.e., those proportional to \( \delta/2 \) in equations 6,7) are pseudoscalars of the general form \( h k \times E \cdot \langle F \rangle \)

where \( h \) is the photon helicity, \( k \) is the photon wave vector, and \( F \) is the atomic angular momentum in the \( 7^{2}P_{1/2} \) state. Although the pseudoscalar term arises from interference between \( \varphi \) and \( \delta F \) and/or \( \delta E \) we express it in terms of \( \delta \), since the latter quantity is measured more accurately than either \( M \) or \( \varphi \) separately in the present experiment.

We analyze the \( 7^{2}P_{1/2} \) polarization by selective excitation of the \( m_P = +1 \) or \( -1 \) components of this state to the \( 8^{2}S_{1/2} \) state, using circularly polarized 2.18\( \mu \) light, directed along \( -z \), and we observe the intensity of 323 nm (\( 8^{2}S_{1/2} \) - \( 6^{2}P_{3/2} \)) fluorescence (See Fig. 2b). The analyzing power of this method is approximately 0.7. Fig. 3 is a schematic diagram of the apparatus, which we now describe in detail.

The cell consists of a "main" section which encloses the electric field region, and a "stem" section, the thallium reservoir. These are constructed of fused quartz, and are supported by a pumpout tube which is normally kept closed by means of a remotely actuated ground quartz
ball-and-socket valve. Surrounding the cell are the "main" and "stem" ovens, which are electrically heated stainless steel (see Fig. 4). The cell body consists of a suprasil cylinder (Amersil Corp.) of 69 mm o.d., 2 mm. wall thickness, fused to top and bottom fused quartz end-plates. The cylinder was carefully selected for high optical quality. The electrodes are flat tantalum plates, 1 mm. thickness, suspended from the cell ceiling by quartz rods and spacers. The electrode separation is 14 mm. The connecting tantalum wires pass through closely fitting quartz capillary tubes to tungsten-glass feedthroughs in the cold portion of the cell assembly. Thallium condenses in the capillaries and seals them.

The stem is a 5 mm. o.d. quartz tube below the main body of the cell. It contains a tantalum crucible which is loaded with 99.999% pure thallium metal with the natural isotopic abundances (29.5% Tl$^{203}$, 70.5% Tl$^{205}$). During the experiment the stem temperature is maintained at about 920° K (corresponding to a Tl vapor density $n \approx 10^{15} \text{ cm}^{-3}$) and the main portion of the cell is at about 1000° K. The cell-oven assembly is surrounded by three concentric cylindrical stainless-steel heat shields and mounted inside a rough vacuum tank. The pressure in the latter is deliberately maintained at about 5 x $10^{-3}$ torr with a controlled air leak so that oven surfaces remain oxidized. This minimizes the presence of chromium and/or manganese vapor which attacks quartz at 1000° K.

The experiment employs two essentially identical flash-lamp pumped tunable pulsed dye lasers (L1, L2), built in this laboratory. Details of design and construction have been reported elsewhere$^{20}$. L1 operates at
585 nm and is used to produce 293 nm light in a doubling crystal for the \( ^2P_{1/2} \rightarrow ^2P_{1/2} \) transition. The pulse is 0.5 μs FWHM and approximately 1 GHz in bandwidth. The frequency is actively stabilized by computer control of intracavity optics. Typical output energy is 10-12 mJ/pulse at a repetition rate of 20 s\(^{-1}\). Laser L-2 delivers 6-7 mJ/pulse with a bandwidth of approximately 15 GHz. The two lasers are synchronized and have a relative time jitter of less than 5 ns.

Light from L1 is focused with an \( f = 62 \text{ cm} \) lens into a \( 0.5 \text{ cm} \times 0.5 \text{ cm} \times 5.0 \text{ cm} \) crystal of \( \text{NH}_4\text{H}_2\text{AsO}_4 \) (ADA) for second harmonic generation. The crystal is temperature stabilized to maintain a 90° phase match condition. Typically we generate 0.6 - 0.7 mJ/pulse at 293 nm. Light emerging from the ADA crystal is linearly polarized vertically, orthogonal to the 585 nm pump beam. A Glan-air calcite prism is used to separate the beams and define the uv linear polarization precisely before the beam enters the circular polarizer. The latter is a Pockels cell (Inrad) consisting of a 2 cm crystal of KD\(_2\)PO\(_4\) (KD\(_2\)PO\(_4\)) aligned with its principal axis along the beam direction. Application of about ±1000 V to the Pockels cell's electrodes results in ± \( \lambda/4 \) retardation. The voltage is pulsed to eliminate the effects of long term relaxation in the retardation which occurs with a dc electric field, and a slow (100 μs) rise time is chosen to avoid crystal resonances. Initial alignment of the Pockels cell is made optically and final alignment makes use of the Stark effect in thallium itself (see Sec. 4.3). The sign of helicity of the uv beam as a function of Pockels cell polarity has been determined optically and by observation of the \( \alpha-\beta \) interference in thallium. (See eqn. 11).
The 2.18 μ light is produced by a Chromatix CMX-4/IR Optical Parametric Oscillator (OPO) driven by L2. The resonant wave in the OPO has λ = 800 nm, and the difference wavelength is 2.18 μ with a bandwidth of 2 cm⁻¹ (Chromatix specification) and a spectral profile with the same mode spacing as the pump (150 MHz). This is sufficient to saturate the \(^7\)P\(_{1/2}\) – \(^8\)S\(_{1/2}\) transition, which has a Doppler width of 230 MHz. Typically we obtain 0.2 – 0.3 mJ/pulse, which is attenuated by 50% before entering the cell to maximize analyzing power. Frequency jitter causes 10-15% signal fluctuations per pulse. The 2.18 μ beam is split into two beams of equal intensity with a thin wafer of polished silicon. The two beams pass through individually adjustable linear polarizers (Polaroid HR plastic) and crystalline quartz quarter-wave plates (Virgo Optics) set to produce beams of opposite helicity in the two interaction regions defined by intersection with the uv beam (See Fig. 3). The fractional difference between signals observed in these two regions is proportional to the polarization \(P_z\) and quite independent of pulse-to-pulse intensity fluctuations of the light beams. The quarter wave plates are rotated automatically about their axis parallel to \(\hat{x}\) once every 128 pulses to reverse the helicity in each region. The 2.18 μ beams are aligned perpendicular to the 293 nm beam to within 1°. A computer controlled solenoid-actuated flag automatically blocks the 2.18 μ beam for background measurements.

The adjustable linear polarizers compensate for imperfections in the orientation of the quarter wave plates. We monitor the signal size asymmetry

\[
p_{1,2}^{\text{ir}} = \frac{S_{1,2}(\text{ir}+)}{S_{1,2}(\text{ir}+)} - \frac{S_{1,2}(\text{ir}-)}{S_{1,2}(\text{ir}-)}
\]
where \( \text{ir}^\pm \) refers to the helicity of the infrared light, and 1, 2 refer to regions. By adjusting the rotational orientation of the linear polarizers \( \Gamma^1_{\text{ir}} \) and \( \Gamma^2_{\text{ir}} \) can be made equal and both \( \leq 10^{-3} \). Because the 7P-8S transition is heavily saturated, the asymmetry in the admixture of incorrect polarization when \( \Gamma^r_{\text{ir}} = 10^{-3} \) is only \( \sim 2 \times 10^{-5} \). This equalizes the analyzing power for \( \text{ir}^+ \) and \( \text{ir}^- \) in each region (although the analyzing power is different in the two regions). By direct measurement, the intensity ratio is:

\[
\frac{I(\text{desired helicity})}{I(\text{unwanted helicity})} = \frac{.001}{.0025} \quad \text{in region 1.}
\frac{I(\text{desired helicity})}{I(\text{unwanted helicity})} = \frac{.001}{.0025} \quad \text{in region 2.}
\]

The rough vacuum tank contains an off-axis rotating window in the front, through which the 293 nm beam enters. This is rotated from time to time by hand so that the uv beam enters through a clean portion of the window. The dielectric mirror at the rear of the tank is used to reflect the uv beam back through the cell. It is back-surfaced so that contaminants from the oven cannot damage the dielectric film. The mirror is mounted off-axis on a rotating seal to allow selection of locations on the mirror which are clean and have minimal birefringence. The reflected beam can be blocked automatically by a solenoid-actuated flag controlled by the computer.

Water cooled magnetic field coils capable of producing \( \pm 8 \) gauss along the x (uv beam) direction are mounted inside the vacuum tank. These are used for diagnostic purposes (See Sec. 4.7). Large diameter coils outside the vacuum system are used to cancel the earth's field and to generate a large magnetic field in the y direction for observation of the Hanle effect (See Sec. 4.5).
Each interaction region is viewed by two photomultiplier tubes. The 323 nm fluorescence accompanying $8S_{1/2} - 6P_{3/2}$ decay is collimated by 38 mm dia f/1 fused silica lenses inside the oven, passes through holes in the heat shields and then through double quartz windows in the detector ports. These windows are cooled by a flowing filtered solution of Phthalic acid (6 g potassium acid phthalate per liter distilled H$_2$O). This solution is a liquid filter with a sharp low-pass cutoff at about 310 nm$^{21}$. Next in line is an interference filter at 323 nm (peak transmission 25-30%, fwhm 2.5 nm) which also contains a UG-11 infrared and visible blocking filter. Finally there is a spatial filter consisting of a 38 mm dia. f/1 quartz lens and an aperture at the focus.

The photomultipliers are 9780 QB (EMI) with bialkali photocathodes and quartz windows. The anodes of the two tubes viewing each region are connected together and capacitively coupled to charge integrating preamplifiers. The output pulse is amplified, digitized and sent to an LSI-11/2 computer.

No component introduces electronic or digitizing noise greater than $10^{-3}$ of the signal, per pulse. A typical signal at each photomultiplier cathode on the 0-1 resonance at a Stark field of 215 V/cm is $10^4$ photoelectrons per pulse. The signal-to-background ratio for these conditions is about 10:1. Most of the background is due to scattering and fluorescence of 293 nm laser photons in the cell walls. The remainder arises from atom-atom collisions and miscellaneous small effects.

For linearly polarized uv light with polarization $\hat{E}$, only the $F = 0 - F' = 0$ transition is allowed for $\parallel \hat{E}$, while for $\perp \hat{E}$, only the 0-1 transition can occur. This fact is used to monitor the frequency of the light. (Here we ignore the 1-1,1-0 transitions which are separated from the 0-0, 0-1 transitions by about 21 GHz.) After the uv laser beam is reflected
back through the main cell and rough vacuum tank, it suffers two 90°
reflections from aluminum mirrors with orthogonal planes of incidence.
The retardation effects of each reflection cancel, leaving the beam
circularly polarized but travelling parallel to -z (See Fig. 3). It then
passes through a fixed quarter wave plate which changes the ±
helicity photons into alternative \( \hat{e}_x \) or \( \hat{e}_y \) linear polarizations. The beam
enters a second vacuum tank which houses a separate oven and thallium
cell with external electrodes. The fluorescence \((7^{2}P_{\frac{1}{2}} \rightarrow 7^{2}S_{\frac{1}{2}} \rightarrow 6^{2}P_{\frac{3}{2}})\)
at 535 nm from this cell is viewed by a single phototube. Observation of
the signal asymmetry between \( I(\hat{e}_x) \) and \( I(\hat{e}_y) \) determines the frequency
directly in terms of the ratio \( I(0^{-1})/I(0^{-0}) \). This ratio, corrected for
background dilution, is averaged over 256 pulses by the computer, which
uses the result to tune L1. An intensity ratio \( I(0^{-1})/I(0^{-0}) = 15 \) is
maintained in the monitor cell, which corresponds to the ratio
\( I(0^{-1})/I(0^{-0}) = 11 \) in the main cell. The discrepancy is caused by higher
efficiency for pumping \( F = 0, m_F = 0 \) \( 7^{2}P_{\frac{1}{2}} \) atoms to the \( 8^{2}S_{\frac{1}{2}} \) state,
than for \( F = 1, m_F = \pm 1 \) atoms.

3. Selective Excitation and Analyzing Power

The selective excitation of \( 7^{2}P_{\frac{1}{2}} \) atoms to the \( 8^{2}S_{\frac{1}{2}} \) state by 2.18\( \mu \)
circularly polarized light may be calculated in a straightforward way
using coupled rate equations for the 8 Zeeman levels. The solution yields
the signal size in the 323 nm channel, compared to the 535 nm signal which
would be observed if all \( 7^{2}P_{\frac{1}{2}} \) atoms were allowed to decay via \( 7S \). When
laser L1 is tuned to the 0-1 transition, 6% of the atoms excited to
\( 7^{2}P_{\frac{1}{2}} \) decay at 323 nm, while on the 0-0 transition, the fraction is 10%.
The calculations also yield the polarization analyzing power at the frequencies where data are taken, vs. 2.18\mu light intensity, and as a function of purity of 2.18\mu circular polarization. The effects of these can be seen in figure 5. As the infrared intensity increases, the 323 nm signal saturates. Further increase eventually causes a dilution in the measured polarization, due to imperfect 2.18\mu photon helicity.

The analyzing power has been measured by observing an interference between \alpha and \beta Stark amplitudes in the 1-1 line. Excitation by circularly polarized uv produces a large polarization \( P_x \) of the \( 7^2P_{1/2} \) state along the +x axis:

\[
P_x(1-1) = \pm \frac{4 \alpha \beta}{3 \alpha^2 + 2 \beta^2} \approx 0.76
\]

(11)

for \pm 293 nm helicities respectively. We have performed an experiment in which the 2.18\mu circularly polarized beam propagates along -x, opposite to the 293 nm beam. The 323 nm fluorescence exhibits a very large asymmetry depending on uv and ir helicities, arising from \( P_x(1-1) \). Observations of this asymmetry yield a measured analyzing power of about 70\%, in agreement with calculations of selective excitation.

4. Analysis of Systematic Errors and Corrections

4.1 General Remarks

Certain important features of the apparatus and experimental procedure are utilized to reduce or eliminate possible systematic errors. These are as follows:
a) All parity data are taken on the \( \left( ^2P_{1/2}, F = 0 \rightarrow ^2P_{1/2}, F' = 1 \right) \) transition (0-1 line). The polarization for the 0-1 line is about 4.5 times greater than for the 1-1 line (although the total signal is about 7 times less). More important, the 0-1 line is much less susceptible to possible systematic errors than the 1-1 line.
b) Two interaction regions, with opposite i.r. circular polarizations, are used (as described in Sec. 2).
c) The electric field polarity is reversed with each pulse.
d) The sign of uv helicity, determined by Pockels cell voltage polarity, is given by the sequence:

\[
+++--+++-++-\ldots
\]

The sequence begins in a random place after each set of 128 pulses. It is chosen to eliminate correlations between E polarity and uv helicity.
e) The ir circular polarization reverses after 128 pulses.
f) The \(^2P_{1/2}\) polarization consists of a parity nonconserving part \( \mp 2 \Im \&/BE \) and a parity conserving part \( -2M/\beta E \). The latter reverses with direction of uv beam and is largely cancelled when the mirror is used. Data are taken with the mirror blocked, and with it unblocked. Background measurements (in which no i.r. reaches the interaction regions but other conditions are the same as for signal) also are taken with and without the mirror. Observations of the parity asymmetry are also carried out on the 0-0 line, as a null experiment.

As will be discussed in detail in Secs. 4.3-4.7 the remaining sources of possible systematic error not eliminated by these precautions are (1) imperfect uv circular polarization, (2) misaligned electric fields which do not reverse exactly in proportion to the main component of electric
field, and (3) magnetic fields. It will be shown that these effects can be measured precisely by a combination of auxiliary experiments, and corrections applied with very small uncertainty.

4.2 Data Collection

Three digitized signals are received from the computer on each pulse: one from each of the interaction regions \((T_1, T_2)\), and one from the monitor cell. We have \(T_{1,2} = S_{1,2} + B_{1,2}\) where \(S, B\) denote signal and background, respectively. The \(T_1, T_2\) are compiled into 16 sums denoted by the array \(T_{ijkl}\). Subscripts \(ijkl\) are given by the following table:

| i = 0,1 | uv pol ± |
| j = 0,1 | E ± |
| k = 0,1 | ir pol ± |
| \(\ell = 1,2\) | Region 1,2 |

After 256 pulses the \(T_{ijkl}\) are stored on disk. Eight polarizations \(P\) are computed by subtracting the regions:

\[
P_{ijk} = \frac{T_{ijkl} - T_{ijk2}}{T_{ijkl} + T_{ijk2}}
\]

The following quantities are formed:

\[
\Delta_M = \frac{1}{8} \left[ (P_{000} - P_{001} - P_{010} + P_{011}) + (P_{100} - P_{101} - P_{110} + P_{111}) \right]
\]

\[
\Delta_P = \frac{1}{8} \left[ (P_{000} - P_{001} - P_{010} + P_{011}) - (P_{100} - P_{101} - P_{110} + P_{111}) \right]
\]

\[
\Delta_E = \frac{1}{8} \left[ (P_{000} - P_{001} + P_{010} - P_{011}) - (P_{100} - P_{101} - P_{110} + P_{111}) \right]
\]

Apart from background and residual systematic effects, to be discussed below, \(\Delta_M\) is the polarization due to M1-Stark interference: \(-2\Delta_M/\beta E\), and \(\Delta_P\) is the parity nonconserving polarization: \(-2 \text{ Im } (\delta_P)/\beta E\). \(\Delta_E\) and other signals and
asymmetries calculated from the $T_{ijkl}$ are used for diagnostic purposes and corrections to the data. The data collection sequence is discussed further in Sec. 5.1.

4.3 The Effects of Imperfect uv circular polarization

Various dilutions of the $M_1$-Stark polarization occur because of background, small admixture of 0-0 intensity in the 0-1 line, and imperfection of the 2.18μ polarization. In addition the $M-1$ Stark interference depends on $k_2$ and is thus reduced by reflections. If any of these dilutions vary as a function of uv circular polarization, this results in a uv polarization-dependent observed $M_1$ asymmetry which would be interpreted as a (false) parity asymmetry. However, the net effect can be expressed in terms of experimentally measured parameters.

The measured $M_1$ asymmetry may be written:

$$\Delta M = D_{\text{i.r.}} \frac{S_f - S_r}{(S + B)} \Delta_{M_0}$$

(16)

where $\Delta_{M_0}$ is the undiluted $M_1$ asymmetry, $D_{\text{i.r.}}$ is the i.r. analyzing power, and $S_f$, $S_r$ are the signals in the 0-1 line for the forward and reflected uv beam respectively. $D_{\text{i.r.}}$ cancels in the ratio $\Delta_F/\Delta_M$ so we ignore it in the following.

For data taken with the mirror blocked, it can then be shown that (16) becomes:

$$\Delta M = \frac{S_b}{(S + B)_b} \frac{1}{(f + 1)} \frac{(1 - r)}{(1 + r)} \Delta_{M_0}$$

(17)

where $f = S_{00}/S_{01} = 0.09$, $r$ is the effective reflectance of the quartz cell, and $b$ stands for "blocked data". The false parity asymmetry is then

$$\Delta_F = \frac{\Delta_{M+} - \Delta_{M-}}{2}$$

(18)
where we employ $\Delta_{M \pm}$ for ± uv circular polarization. It can be shown that (18) becomes:

$$
\Delta_{F}^{b} = \Delta_{M b} \left( \frac{1 + f}{1 - f} \right) \left[ \frac{B_{b}}{S_{b}} (\Gamma_{b} - \gamma_{b}) + \frac{2f}{1 + f} \Gamma_{b} \right]
$$

(19)

where

$$
\Gamma_{b} = \frac{(S + B)_{b+} - (S + B)_{b-}}{(S + B)_{b+} + (S + B)_{b-}}
$$

and

$$
\gamma_{b} = \frac{B_{b+} - B_{b-}}{B_{b+} + B_{b-}}
$$

The first term in (19) is due to asymmetric background dilutions, the second to 0-0 contamination. Each of the quantities on the RHS of (19) is measured during data collection. Fine adjustment of the Pockel cell voltage is made during data collection to minimize $\Gamma_{b}$ which is nonzero primarily because of polarization imperfections.

Most of our data were collected with the mirror unblocked. This was done to increase signal and reduce systematic effects associated with $\Delta_{M}$ (the latter is decreased by about a factor of 4 when the mirror is unblocked). However, the uv polarization does suffer a slight degradation on reflection from the mirror, which is back-surfaced, and this can also result in a difference $S_{f} - S_{r}$ which depends on uv circular polarization. It can be shown that in the "unblocked" case:

$$
\Delta_{F u}^{b} = \Delta_{M b} \left( \frac{1 + f}{1 - f} \right) \frac{(S + B)_{b}}{S_{b}} \frac{b_{u}}{b_{b}} \left[ 2(S + B)_{b} (\Gamma_{b} - \Gamma_{u}) + 2b_{b}(\Gamma_{u} - \gamma_{b}) + b_{u}(\gamma_{u} - \Gamma_{u}) \right] + \frac{2f}{1 + f} (2S_{b} - S_{u}) \gamma_{u}
$$

(20)
The subscript u refers to "unblocked". The first term on the RHS of (20) accounts for forward and reverse beam polarization asymmetries. The other terms describe the dilutions already discussed; all are expressed in terms of measured quantities. It has been assumed in this discussion that the effective reflectance of the front and rear of the cell are the same.

4.4 The Effects of Misaligned Electric Fields

A static electric field of ±215 V/cm exists in each interaction region during each pulse. Ideally the field is along the y axis perpendicular to \( k_b \) (along \( \hat{x} \)) and \( \hat{z} \) (the i.r. beam direction). In reality \( k_b \) defines \( \hat{x} \) and the 2.18\( \mu \)m beam(s) define the \( \hat{x} - \hat{z} \) plane. \( \mathbf{E} \) may then have \( x, y, \) and \( z \) components, and \( \mathbf{E}_+ , \mathbf{E}_- \) may differ slightly in magnitude and direction.

We now analyze the consequences of this, assuming the uv light is perfectly circularly polarized:

\[
\mathbf{E}_\pm = \frac{\hat{y} \pm \mathbf{i} \hat{z}}{\sqrt{2}}.
\]

Assuming \( \mathbf{E} = \mathbf{E}_x \hat{x} + \mathbf{E}_y \hat{y} + \mathbf{E}_z \hat{z} \), a finite \( 7^2P_{1/2} \) polarization appears for the 0-1 transition even in the absence of \( M \) and \( \mathbf{E}_\alpha \) amplitudes:

\[
P_E = \mp \frac{2\mathbf{E}_x \mathbf{E}_z}{\mathbf{E}_y^2} \quad \text{for } \mathbf{E}_y^2 >> \mathbf{E}_x^2, \mathbf{E}_z^2.
\]

(21)

\( P_E \) reverses with uv circular polarization and behaves the same in this respect as \( \Delta_P \). However if \( E \) reverses exactly \( P_E \) remains unchanged, unlike \( \Delta_P \). Therefore \( P_E \) contributes a false parity asymmetry \( \Delta_f \) only if \( \mathbf{E}_0 \) does not reverse exactly. We separate \( \mathbf{E} \) into reversing and non-reversing components:

\[
\mathbf{E}_+ = \mathbf{E}_0 + \Delta \mathbf{E}, \quad \mathbf{E}_- = - \mathbf{E}_0 + \Delta \mathbf{E}
\]

(22)
Assuming \( E_{0y} \gg \Delta E_y, E_{0x}, \Delta E_x, E_{0z}, \Delta E_z \), we find

\[
\Delta \rho \approx -\frac{(2E_{0x} \Delta E_z + 2E_{0z} \Delta E_x)}{E_{0y}^2} + \frac{4E_{0x} E_{0z} \Delta E_y}{E_{0y}^3}
\]  \hspace{1cm} (23)

The quantities \( \Delta E_y, E_{0x}, \Delta E_x, E_{0z}, \Delta E_z \) are determined experimentally (see Sec. 4.7).

4.5 Magnetic Fields

Two magnetic field effects can contribute false parity asymmetries: hyperfine mixing, and precession of \( ^2P_{1/2} \) polarization components \( P_x, P_y \) into the \( z \) direction due to magnetic fields \( B_y, B_x \) respectively (Hanle effect).

a) Hyperfine mixing.

An external magnetic field mixes states of different \( m_F \). We define the quantities

\[
\omega_n = \frac{g_1 \mu_B B_i}{2 \hbar \Delta \nu} \frac{n}{n}
\]  \hspace{1cm} (24)

where \( \Delta \nu_n \) is the hyperfine splitting of the \( n^2P_{1/2} \) state. To lowest order in the magnetic field the 0-1 \( ^2P_{1/2} \) polarization is:

\[
P = \pm \frac{2M_B}{BE} \left( \omega_x - \omega_y \right) \frac{\alpha}{\beta}
\]  \hspace{1cm} (25)

where \( E \) is assumed to be in the \( y \) direction. This polarization, like \( \Delta \rho \), reverses with UV circular polarization and \( E \). It yields a false parity asymmetry equal to that expected for \( \Delta \rho \) when \( |B_x| = 5.5 \text{ gauss} \). However, during the experiment \( B_x \ll .01 \text{ g} \), so this effect is small and we ignore it in the following discussion.
b) Hanle Effect

The large polarization $P(1-1)$ along $x$ for the 1-1 line (Eq. 11) can be made to precess into the $\hat{z}$ axis by imposing a magnetic field $B_y$. With an earlier apparatus we observed the circular polarization of the 535 nm decay fluorescence in the $\hat{z}$ direction. Taking into account precession in the $7^2S_{1/2}$ state with a known mean lifetime, we obtained the result:

$$A(7^2P_{1/2} \rightarrow 7^2S_{1/2}) = (2.14 \pm 0.1) \times 10^7 \text{ s}^{-1}. \quad (\text{See Fig. 6})$$

The precession can also be observed in 323 nm fluorescence, although this is complicated because of coupling of $7^2P_{1/2}$ and $8^2S_{1/2}$ states by the $2.18\mu$ circularly polarized laser field. The observations agree reasonably well with calculations of this effect. A measurement of the precession angle $\theta_x$ as a function of magnetic field $B_x$ will be described in Sec. 4.7.

4.6 General Treatment of Systematic Effects

We combine the aforementioned effects and write a general $6^2P_{1/2} (F = 0) \rightarrow 7^2P_{1/2} (F' = 1)$ transition amplitude for a thallium atom in arbitrary electric and magnetic fields. We also allow for imperfect uv circular polarization by writing the nominal $\pm$ polarization states as

$$\hat{R} = \sqrt{1 - \eta^2} \hat{\varepsilon}_+ + \eta e^{i\phi} \hat{\varepsilon}_-$$

$$\hat{L} = \sqrt{1 - \eta'^2} \hat{\varepsilon}_+ + \eta' e^{i\phi'} \hat{\varepsilon}_-$$

respectively, and $\eta, \phi, \eta', \phi'$ are arbitrary real numbers (but $\eta^2 \ll 1, \eta'^2 \ll 1$). We then obtain:
\[ m^I_F = 1: \]
\[
A_\pm = \mp \frac{E \beta}{2} (1 - Q_\pm) \mp \frac{i E}{2} (1 - Q_\pm) + \frac{i E}{2} \beta (1 + Q_\pm) \mp \frac{M}{2} (1 - Q_\pm)
\]
\[
+ \frac{\text{Im}(\mathcal{E}_p)}{2} (1 + Q_\pm) - \frac{E}{2} (1 + Q_\pm) - i \frac{\theta M}{2} (1 + Q_\pm)
\]
\[
- i \frac{E \beta}{2} (1 + Q_\pm) + \frac{M}{2} (1 + Q_\pm)
\]
\[
\pm \frac{i E}{2} \alpha (1 - Q_\pm) \mp \frac{E}{2} \zeta^2 (1 - Q_\pm) + \frac{\theta}{2} (1 + Q_\pm) \mp \frac{i \theta}{2} M (1 - Q_\pm)
\]

\[ m^I_F = 0: \]
\[
A_\pm = -\frac{i E}{\sqrt{2}} \beta (1 + Q_\pm) + \frac{M}{\sqrt{2}} (1 + Q_\pm) \mp \frac{\text{Im}(\mathcal{E}_p)}{\sqrt{2}} (1 - Q_\pm)
\]
\[
+ \frac{\theta E}{\sqrt{2}} (1 - Q_\pm) \mp \frac{i \theta}{\sqrt{2}} M (1 - Q_\pm)
\]
\[
\pm \frac{\theta E \beta}{\sqrt{2}} (1 - Q_\pm) - \frac{i E}{\sqrt{2}} \zeta^2 (1 + Q_\pm)
\]

\[ m^I_F = -1: \]
\[
A_\pm = \pm \frac{E \beta}{2} (1 - Q_\pm) \pm \frac{i E}{2} (1 - Q_\pm) - \frac{i E}{2} \beta (1 + Q_\pm) \pm \frac{M}{2} (1 - Q_\pm)
\]
\[
+ \frac{\text{Im}(\mathcal{E}_p)}{2} (1 + Q_\pm) - \frac{E}{2} (1 + Q_\pm) - i \frac{\theta M}{2} (1 + Q_\pm)
\]
\[
+ \frac{i \theta}{\sqrt{2}} \alpha (1 + Q_\pm) - \frac{\theta}{\sqrt{2}} M (1 + Q_\pm)
\]
\[
\pm \frac{i \theta E}{2} \beta (1 - Q_\pm) \pm \frac{\theta}{2} (1 - Q_\pm) + \frac{\theta}{2} (1 + Q_\pm) \mp \frac{i \theta}{2} M (1 - Q_\pm)
\]
In these expressions \( Q_+ = \eta e^{i\phi} \), \( Q_- = \eta' e^{i\phi'} \), and \( \theta_x, \theta_y, \theta_z \) are small Hanle rotations about the axes \( x, y, z \) respectively. Also terms in \( \eta^2, \eta'{}^2 \), and terms involving hyperfine mixing, and of second order or higher in misalignment, have been omitted.

It may be shown that Eq'ns 28-30 result in the following contributions to the quantities \( \Delta_M, \Delta_P, \) and \( \Delta_E \) defined by Eq'ns 13, 14, 15 respectively:

\[
\Delta_M = -\frac{2M}{\beta E_{0y}} + \frac{2\Delta E_x \theta_z}{E_{0y}} - \frac{2E_{0x} \Delta E_y \theta_z}{E_{0y}^2} + \frac{2M f(\alpha^2/\beta^2)}{E_{0y} \beta(1 + f(\alpha^2/\beta^2))^2} 
\]

\[
+ \frac{2\theta_x \Delta E_y}{E_{0y}} \left( \eta \cos \phi - \eta' \cos \phi' \right) - \frac{2M}{\beta E_{0y}} \left( \frac{E_{0z}}{E_{0y}} + \theta_x \right) \left( \eta \sin \phi - \eta' \sin \phi' \right)
\]

(31)

\[
\Delta_P = -\frac{2 \text{Im}(\xi_p)}{\beta E_{0y}} - \frac{2E_{0x} \Delta E_z}{E_{0y}^2} + \frac{4E_{0x} \Delta E_y}{E_{0y}^2} \left( \frac{E_{0z}}{E_{0y}} - \theta_x \right) - \frac{2\Delta E_x}{E_{0y} \beta(1 + f(\alpha^2/\beta^2))^2} 
\]

\[
- 2 \left( \eta \sin \phi + \eta' \sin \phi' \right) \left( \frac{M}{\beta E_{0y}} \right) \left( \theta_x + \frac{E_{0z}}{E_{0y}} \right) 
\]

\[
- \frac{4 E_{0x} \eta M \theta_y}{\beta E_{0y}^2} \left( \eta \sin \phi + \eta' \sin \phi' \right) 
\]

\[
+ \frac{2\theta_x \Delta E_y}{E_{0y}} \left( \eta \cos \phi + \eta' \cos \phi' \right)
\]

(32)

\[
\Delta_E = -\frac{2E_{0z} E_{0x}}{E_{0y}^2} - \frac{2\Delta E_z \Delta E_x}{E_{0y}^2} + \frac{2\theta_x E_{0z} \Delta E_y}{E_{0y}} - \frac{2\theta_x \Delta E_z \Delta E_x}{E_{0y}^2} 
\]

\[
- \left( \frac{2\Delta E_z M}{\beta E_{0y}^2} \right) \left( \eta \sin \phi + \eta' \sin \phi' \right)
\]

(33)
In Eq'n (32) the leading term gives true parity violation. The next three terms account for the effect of misaligned electric field; the last two of these are modified by the presence of a magnetic field in the x direction, of the next two terms, proportional to \((\eta \sin \phi + \eta' \sin \phi')\), the first depends on \(E_{0z}/E_{0y}\) and is modified by the magnetic field \(B_x\); the second is much smaller and may be ignored. The seventh term describes the 0-0 dilution effect already accounted for in the second term of eq'n 19 and the 4th term of eq'n 20, Sec 4.3. Finally, the eighth term in Eq. (32) is always very small during the experiment, and may be ignored. Thus, after the corrections embodied in Eq'n 19, 20 have been made and small terms have been ignored there remains the following false parity asymmetry:

\[
\Delta_{\text{FALSE}} = -\frac{2E_0x}{E_{0y}} \frac{\Delta E_x}{2} - \frac{2E_0x}{E_{0y}} \left(\frac{E_{0z}}{E_{0y}} - \theta_x\right) + \frac{4E_{0x} \Delta E_y}{E_{0y}^2} \left(\frac{E_{0z}}{E_{0y}} - \theta_x\right) \\
- \frac{2M}{E_{0y}^2} \left(\frac{E_{0z}}{E_{0y}} + \theta_x\right) (\eta \sin \phi + \eta' \sin \phi')
\]

(34)

4.7 Methods of Measuring False Parity Effects

We now describe independent measurements of \(E_{0x}, E_{0z}, \Delta E_x, \Delta E_z, \Delta E_y,\) and \(\eta \sin \phi + \eta' \sin \phi'.\)

a) Information in Parity Data

\(\Delta E_y\): The total signal for each electric field direction, summed over regions and laser polarizations, is \(S(E_\pm) \propto E_{0y}^2 \pm 2E_{0y} E_y\). We measure the asymmetry

\[
\gamma_E \equiv \frac{S(E_+)}{S(E_+)} = \frac{2\Delta E_y}{E_{0y}}
\]

(35)

By adjustment of a resistor network in the E field pulser, we maintain

\[
\Delta E_y \leq 2 \times 10^{-3} E_{0y},
\]
b) Measurements with Linearly Polarized uv.

$\Delta E_z$: This can be measured using linearly polarized light at 45° with respect to the $\hat{y}$ axis. Let $\varepsilon_\pm = \frac{1}{\sqrt{2}} (\hat{y} \pm \hat{z})$. Then it can be shown that the signal sizes for the 0-1, 0-0 lines are:

$$S_{01}(\varepsilon_\pm) \propto \frac{\beta^2 E_z^2}{2} \left( 1 \pm 2 \frac{E_z}{E_y} \right)$$

$$S_{00}(\varepsilon_\pm) \propto \frac{\alpha^2 E_z^2}{2} \left( 1 \pm 2 \frac{E_z}{E_y} \right)$$

respectively. Forming the experimental asymmetries:

$$A(\varepsilon_\pm) = \frac{S_{E+} - S_{E-}}{S_{E+} + S_{E-}}$$

where the subscripts $E_\pm$ refer to electric field orientation, we find

$$\frac{\Delta E_z}{E_{0y}} = \frac{(1 + f) A(\varepsilon_+) - A(\varepsilon_-)}{4}$$

$E_{0z}/E_{0y}$: The linear polarization experiment provides additional information through $\Delta_p$. With $\varepsilon_\pm = \frac{1}{\sqrt{2}} (\hat{y} \pm \hat{z})$, we obtain:

$$\Delta_p = \frac{-2M}{\beta E_{0y}} \left( \theta_x + \frac{E_{0z}}{E_{0y}} \right) = \Delta_M \left( \theta_x + \frac{E_{0z}}{E_{0y}} \right)$$

where in (39) only the most significant terms have been retained. For $\theta_x = 0$, $\frac{E_{0z}}{E_{0y}} = \frac{\Delta_p}{\Delta_M}$. Since this formula applies to both blocked and unblocked data we may use a weighted average of the two results to obtain $E_{0z}/E_{0y}$.

If we now employ a magnetic field $B_x = \pm 5$ gauss, it is possible to determine $\theta_x$ for these fields. The result is $\theta_x (5\text{ gauss}) = 0.22 \pm 0.01$, consistent with the rotation observed in the 1-1 line (Sec 4.5).
c) Measurements Employing Magnetic Fields and Circularly Polarized Light

\( E_{0x}/E_{0y} \): Returning to circular polarization but using the same magnetic fields we form the difference between \( \Delta_E(+\theta_x) \) and \( \Delta_E(-\theta_x) \) to eliminate terms independent of \( \theta_x \) in Eq. (33). Keeping only the significant term we find

\[
\frac{E_{0x}}{E_{0y}} = \frac{\Delta_E(+\theta_x) - \Delta_E(-\theta_x)}{4\theta_x}
\]  

(40)

d) \( \Delta E_x/E_{0y} \) and \( (\eta \sin \phi + \eta' \sin \phi') \):

Forming a similar difference for \( \Delta_p \) one finds

\[
\Delta_p(+\theta_x) - \Delta_p(-\theta_x) = 2\theta_x \left\{ \frac{2\Delta_x}{E_{0y}} + \Delta_M (\eta \sin \phi + \eta' \sin \phi') \right\}
\]

(41)

By comparing this difference for blocked and unblocked data one obtains:

\[
(\eta \sin \phi + \eta' \sin \phi') = \frac{[\Delta_{pb}(+\theta) - \Delta_{pb}(-\theta) - (\Delta_{pu}(+\theta) + \Delta_{pu}(-\theta))]}{2\theta_x (\Delta_{mb} - \Delta_{mu})}
\]

(42)

\[
\frac{\Delta E_x}{E_{0y}} = \frac{\Delta_{pb}(-\theta) - \Delta_{pb}(+\theta) - \Delta_{mb} \Delta_{mu} (\Delta_{pu}(-\theta) - \Delta_{pu}(+\theta))}{2\theta_x (\Delta_{mb} - \Delta_{mu})}
\]

(43)

It should be noted that the measured \( \frac{E_{0x}}{E_{0y}} \), \( \frac{\Delta E_x}{E_{0y}} \), and \( \eta \sin \phi + \eta' \sin \phi' \) are all diluted by the same polarization analyzing power as \( \Delta_p \), whereas \( E_{0z}/E_{0y} \) and \( \frac{\Delta E_z}{E_{0y}} \) are not. As a result, the various products of these terms appearing in \( \Delta_{\text{false}} \) (Eq. 34) all have the same dilutions as \( \Delta_p \).

To summarize, all possible significant false parity asymmetries appear in the foregoing analysis, and all terms have been measured by independent experiments.
5. Data Analysis and Results

5.1 Secondary Data Sets and Auxiliary Data

The sequence in which data are accumulated is shown in Table 1a. During one of these sets (which requires about 40 minutes) signal corrections (Eq.s 19, 20) and normalization are quite constant, since manual adjustments to the apparatus such as mirror rotation and balance of E field are generally done on a longer time scale.

We define a secondary data point as an average of 80 primary points (unblocked) and 48 primary points (blocked). One determines the average parity, M1 and signal asymmetries, and signal sizes necessary to perform the corrections of Eq'ns 19,20. These corrections are calculated separately for each interaction region, averaged, and assigned a statistical uncertainty determined from the combined uncertainty of all the factors in Eq's 19,20.

The net correction is subtracted from $\Delta_{p,\text{obs}}^i$ to obtain $\Delta_{p}^i$ while the uncertainties are combined in quadrature. Each of the $\Delta_{p}^i$ and associated uncertainties are then normalized to $\Delta_{M,b}^i = 9.0 \times 10^{-3}$ to account for the variations in analyzing power between secondary data points which affect parity and M1 asymmetries in the same way. These variations are due to fluctuations in i.r. power and polarization, and changes in background and 0-0 dilution. A weighted average of the normalized $\Delta_{p}^i$ is then taken over a run. (See Tables 2,3).

Interspersed throughout a run at intervals of approximately 10 basic data sets, are sets of auxiliary measurements needed to determine $E_{0x}$, $E_{0x}$, $\Delta E_x$, $\Delta E_y$, and $(\eta \sin \phi + \eta' \sin \phi')$. A typical sequence of auxiliary measurements is shown in Table 1b. In a typical run, there are about 6 such sequences. These measurements must also be corrected with Eq'ns 19, 20. In addition
measurements with $B_x \neq 0$ must be corrected for hyperfine mixing and for reduction of $\Delta N$ by rotation of the polarization away from the $z$ axis. With these precautions $E_{0x}$, $E_{0z}$, $\Delta E_x$, $\Delta E_z$, and $\eta \sin \phi + \eta' \sin \phi'$ can be extracted reliably and precisely.

Results of the auxiliary measurements are displayed by run in Table 4. Quantities $\Delta E_x$, $\Delta E_z$ are fairly constant from first to last run, although perhaps they show a slight increase with time (as the cell degraded gradually). The values of $E_x$ and $E_z$ also remain fairly constant except for deviations associated with adjustments of angles and positions of $L1,L2$ laser beams. The quantity $\eta \sin \phi + \eta' \sin \phi'$ varies more erratically from run to run, since it depends sensitively on Pockels cell alignment, which was reset for each run. There is no indication of variation between re-alignments. The net contribution from this term averaged over all runs is small.

5.2 Results

The normalized average corrections for a given run are subtracted from the weighted average of the normalized $\Delta_p^i$. The statistical uncertainty associated with each correction is combined in quadrature with the statistical uncertainty in the normalized $\Delta_p^i$, for this run. This, finally is a measurement of the parity asymmetry with associated statistical uncertainty. Our total data sample consists of 11 such runs, listed in Tables 2, 3. A weighted average yields

$$\Delta_{Pb} = 1.55 \pm 0.58 \times 10^{-5}$$

$$\Delta_{Pu} = 1.53 \pm 0.45 \times 10^{-5}$$
The data were also treated by applying the field corrections to each secondary data point and then combining. The results of this method are very close to the values quoted.

5.3 Correlation Tests

A correlation study was done on the set of 425 secondary data points, both before and after corrections were applied, to examine the possible dependence of $\Delta_p$ on other system parameters (see Table 5).

Before corrections one finds a high correlation between $\Delta_{p,u}$ and $\Gamma_b - \Gamma_u$ (see eq'n 20) as well as between $\Delta_{p,b}$ and $\Gamma_b$ (see eq'n 19). The only significant correlation surviving after the corrections is between $\Delta_{p,u}$ and $\Gamma_b - \Gamma_u$, and it has reversed sign. This suggests that the correction of Eq'n 20 has been over-estimated (by about 30%). We believe that this is largely due to reflections in the cell, which can only be estimated crudely. Therefore we average the results of our model (Eq. 20) and the predictions of the correlation study, and expand the systematic error to include both possibilities. This lowers the average of $\Delta_{p,u}$ by $0.10 \times 10^{-5}$ from that originally calculated. All other correlations with the corrected data are at an acceptably low level.

5.4 Systematic Uncertainties and Final Results

The systematic uncertainties are summarized in Table 6. Since the sources of these systematic effects are uncorrelated, we combine the uncertainties in quadrature. The final results are

$$\Delta_{p,b} = (1.55 \pm 0.58 \pm 0.06) \times 10^{-5}$$  \hspace{1cm} (46)

$$\Delta_{p,u} = (1.43 \pm 0.45 \pm 0.11) \times 10^{-5}$$  \hspace{1cm} (47)
where the first uncertainty in each equation is statistical and the second is systematic. Since these results are consistent they may be combined to yield the result

$$\Delta_p = (1.48 \pm 0.36 \pm 0.09) \times 10^{-5}$$ (48)

The corrected result for data taken on the 0-0 line is

$$\Delta_{00} = - (0.13 \pm 0.82 \pm 0.02) \times 10^{-5},$$

where no $7^2p_{1/2}$ polarization is expected.

In order to compare with theory we calculate $\delta = 2 \text{ Im } \frac{\xi}{M}$. We take the ratio $2 \Delta_p(0-1)/\Delta_M$ where $\Delta_M = 9.0 \times 10^{-3}$ K. The factor $K$ corrects for reflections from the rear of the main cell, which reduces $\Delta_M$ but not $\Delta_p$. We estimate $K = 1.17$, but it might be somewhat smaller, which leads to a skewness in our final result,

$$\delta = (2.8 \pm 0.7 \pm 0.3) \times 10^{-3}$$ (49)

This result is consistent with theory, (see Eq'n 5).

6. Conclusions

The result (49) may be expressed in terms of $Q_W$, which is defined as

$$Q_W^S = Z(1 - 4 \sin^2 \theta_W) - N$$

in the standard model, and takes the values $Q_W^S(Tl^{205}) = -117.5$, $Q_W^S(Tl^{203}) = -115.5$ for $\sin^2 \theta_W = 0.23$. We find

$$Q_W,\text{ expt} (Tl) = -155 \pm 63$$ (50)

where the uncertainty includes that in $(\xi_p)_{\text{theo}}$ as well as the uncertainty in $\delta_{\text{expt}}$. 
The results of electron scattering and atomic physics experiments in Tl and Bi may be combined with neutrino-nucleon and neutrino-electron scattering data to provide a stringent test of neutral weak interaction theories. In carrying out this analysis it is useful to employ the simplest model-independent assumptions, as was done by Hung and Sakurai. They show that if one merely assumes weak universality, that the contributions of heavy quarks, c, s, ... may be neglected, and that all neutral weak currents possess only V and A components, then the theory is characterized by 10 coupling constants \( \tilde{\alpha}, \tilde{\beta}, \tilde{\gamma}, \tilde{\delta}, \alpha, \beta, \gamma, \delta, g_\nu \) and \( g_A \), which must be determined by experiment. The neutrino-nucleon scattering data completely determine \( \alpha, \beta, \gamma, \) and \( \delta \) (up to an overall sign ambiguity), while neutrino-electron scattering results determine \( g_\nu, g_A \) up to a (two-fold) \( V,A \) ambiguity. The polarized electron scattering experiment yields

\[
\tilde{\alpha} + \frac{1}{3} \tilde{\gamma} = -0.60 \pm 0.16, \quad \tilde{\beta} + \frac{1}{3} \tilde{\delta} = 0.31 \pm 0.51
\]  

(51)

The heavy atom experiments are sensitive to an almost orthogonal linear combination of \( \tilde{\alpha} \) and \( \tilde{\gamma} \):

\[
Q_w(Tl) = 42\tilde{\alpha} - 612\tilde{\gamma}
\]  

(52)

As Hung and Sakurai have noted, further restrictions on the coupling constants are obtained if one assumes the "factorization" hypothesis. Employing result (50), formula (52), and factorization we represent the resulting constraints on \( \tilde{\alpha} \) and \( \tilde{\gamma} \) in fig. 7 and obtain:

\[
\tilde{\alpha} = -0.69 \pm 0.16 \quad \text{(53)}
\]

\[
\tilde{\gamma} = +0.23 \pm 0.08 \quad \text{(54)}
\]
Assuming factorization, Hung and Sakurai show that all 10 constants are determined without ambiguities and are in excellent agreement with predictions of the standard model for $\sin^2 \theta_W = 0.23$. Without factorization $\tilde{\beta}$ and $\tilde{\delta}$ remain undetermined experimentally.

A substantial improvement in the measurement of $\text{Im} \left( \frac{\mathcal{E}_p}{\beta} \right)$ for the $6^2P_{1/2} - 7^2P_{1/2}$ transition in Tl seems possible by means of a technique utilizing linearly polarized 293 nm light and an external magnetic field. This experiment is being pursued in our laboratory. The 30% uncertainty in the theory comes from the one-electron central field atomic wave functions used to calculate $\mathcal{E}_p$ and $\beta$. In principle this could be improved to 15% by a precise measurement of $\beta$.

Acknowledgements

We thank S. Chu and R. Conti for invaluable contributions to the early phases of the experiment, and D. Neuffer for calculations. We are grateful to P. Drell for many discussions and useful assistance, and glassblowers D. Anderberg and R. Hamilton for excellent workmanship. This research was done under the auspices of the Chemical Sciences Division, Office of Basic Energy Sciences, U.S. Department of Energy, under Contract No. W-7405-ENG-48.
