ABSTRACT

Torsional hydromagnetic waves are generated in a cylindrical hydrogen plasma. The device that generates the plasma is described. Spectroscopic observation of Stark-broadened Balmer lines gives the ion density as a function of time and indicates that the plasma is highly ionized. Reflections of the hydromagnetic waves are observed from high- and low-impedance boundaries, and from a plasma–neutral gas interface. The phases of the reflected waves are found to agree with theory. The driving current that generates the waves is analyzed in terms of Newcomb’s principal modes. The measured radial distribution of the wave magnetic field is in fair agreement with this analysis. Two different types of measurement suggest that the decaying plasma is electrically isolated from the (conducting) walls.

INTRODUCTION

This paper reports an extension of previous experimental work with Alfvén waves. We consider hydromagnetic waves propagating in a cylindrical plasma in a uniform axial magnetic field, as shown in Fig. 1. The copper tube is filled with highly ionized plasma by an electrically driven switch-on ionizing wave (by a process which will be described). After the tube is filled with plasma a hydromagnetic wave is induced by a radial current flow from the small molybdenum electrode (at the left of Fig. 1) to the copper tube. The force produced by this radial current together with the static axial magnetic field displaces the plasma in the azimuthal ($\theta$) direction, and a transverse wave is propagated in the axial direction, along magnetic field lines. The transient magnetic field which is associated with the wave is also in the azimuthal direction.

THEORY

The problem of torsional hydromagnetic waves propagating in a cylindrical plasma has been treated by a number of authors. We shall follow Newcomb and include finite conductivity. Azimuthal symmetry is assumed (see discussion on Generation of Waves), and we will look for solutions to the equations in which the various field quantities have the form

*Work done under the auspices of the U.S. Atomic Energy Commission.
\( F(x) e^{i(pz - \omega t)} \), i.e., are plane waves with sinusoidal time variation, propagating only in the \( z \) direction. Displacement current, viscosity, and plasma pressure are neglected. The wave frequency (\( 3 \times 10^6 \) radians/sec for this experiment) is assumed low with respect to the ion cyclotron frequency (typically \( 1.5 \times 10^8 \) radians/sec for this experiment). We use rationalized MKS units in this discussion. We begin with the linearized form of Maxwell's equations, Ohm's law, and Newton's second law of motion:

\[
\begin{align*}
\nabla \times \mathbf{B} &= \mu_0 \mathbf{j}, \\
\nabla \times \mathbf{E} &= -\frac{\partial \mathbf{B}}{\partial t}, \\
\mathbf{E} + \mathbf{v} \times \mathbf{B} &= \frac{j}{\sigma}, \\
\rho_0 \frac{\partial \mathbf{v}}{\partial t} &= j \times \mathbf{B}_0,
\end{align*}
\]

where \( \mathbf{B} \) is oscillating magnetic field associated with the wave, \( \mathbf{j} \) is the current density associated with the wave, \( \mathbf{E} \) is the wave electric field, \( \mathbf{v} \) is the plasma velocity, \( \mathbf{B}_0 \) is the static axial magnetic field supplied by external coils, \( \rho_0 \) is the plasma mass density, \( \sigma \) is the plasma conductivity, and \( \mu_0 \) is the permeability of free space. Introducing the \( e^{-i\omega t} \) dependence and solving Eqs. (1) to (4) for the wave magnetic field \( \mathbf{B} \) yields

\[
\frac{\partial \mathbf{B}}{\partial t} + \frac{1}{\mu_0 \omega \rho_0} \nabla \times \left\{ \mathbf{B}_0 \times \left[ \nabla \times \mathbf{B} \right] \right\} - \frac{1}{i \mu_0 \omega \sigma} \nabla \times \nabla \times \mathbf{B} = 0.
\]

This can be simplified to give

\[
\nabla^2 \mathbf{B} + \frac{\partial^2 \mathbf{B}}{\partial z^2} - i \alpha \nabla^2 \mathbf{B} - \nabla \frac{\partial \mathbf{B}}{\partial z} + \frac{\omega^2}{V^2} \mathbf{B} = 0,
\]

where

\[
\alpha = \frac{\mu_0 \omega}{\sigma}.
\]
where we have introduced the Alfvén velocity, \( V = B_0/(\mu_0 \rho)^{1/2} \), and the dimensionless parameter, \( a = \omega/(\mu_0 \sigma V^2) \); \( \dot{z} \) is defined by \( \dot{z} = \frac{B_0}{B_0} \).

The component of Eq. (6) which is perpendicular to \( \dot{z} \) is

\[
\frac{\partial^2 b_\perp}{\partial z^2} - i a V^2 b_\perp - \frac{\partial b_z}{\partial z} + \frac{\omega^2}{V^2} b_\perp = 0,
\]

where \( v_\perp \) is the perpendicular component of the gradient operator. Inserting the \( e^{ipz} \) dependence and rearranging, we have

\[
v_\perp^2 b_\perp + k_c^2 b_\perp + \frac{p}{a} v_\perp b_\perp = 0, \tag{7}
\]

where we define

\[
k_c^2 = -p^2 (1 + \frac{i}{a}) + \frac{i \omega^2}{a V^2}. \tag{9}
\]

We are interested in the equation for \( b_\theta \), which comes from the azimuthal component of Eq. (8). In cylindrical coordinates this is

\[
\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial b_\theta}{\partial r} \right) - \frac{b_\theta}{r^2} + k_c^2 b_\theta = 0. \tag{10}
\]

Then the general solution that is regular at \( r = 0 \) is

\[
b_\theta = \sum_{n=1}^{\infty} b_{\theta n} J_1 (k_{cn} r) \exp \left[ i (p_n z - \omega t) \right], \tag{11}
\]

where \( J_1 (k_{cn} r) \) is the first-order Bessel function, and \( n \) designates the mode of propagation. This type of wave is called a principal mode by Newcomb. 3

The \( b_{\theta n} \) are constants determined by the form of the initial perturbation that induces the wave, and the \( k_{cn} \) are constants determined by a radial boundary condition. Experimentally, we shall find that one or two of the principal modes are sufficient to describe the observed distributions. The other wave quantities can be obtained from substitution in Eqs. (1) to (4):
The attenuation of the various principal modes that is caused by ohmic losses will be needed for the analysis of the experimental results. If we set

\[ p_n = k_n + i/L_n, \]

where \( k_n \) is the propagation constant, and \( L_n \) is the attenuation length for the \( n \)th principal mode (i.e., the distance in which a wave amplitude decreases to \( 1/e \)), then separating real and imaginary parts of Eq. (9) yields, in the case \( \alpha^2 \ll 1, \quad \alpha^2 (k_{cn} V/\omega) \ll 1, \)

\[ E_r = \sum_{n=1}^{\infty} \frac{p_n}{\mu_0} \left( \frac{V^2}{\omega} - \frac{i}{\mu_0 \sigma} \right) b_{\theta n} J_1 (k_{cn} r) \exp \left[ i (p_n z - \omega t) \right], \]

\[ E_z = \sum_{n=1}^{\infty} \frac{k_{cn}}{\mu_0 \sigma} b_{\theta n} J_0 (k_{cn} r) \exp \left[ i (p_n z - \omega t) \right]. \]

Thus to the order of approximation given above the waves have no dispersion and no cutoff.
Analysis of Initial Disturbance into Radial Modes

The coefficients $b_{\theta n}$ appearing in Eqs. (11) through (16) are the amplitudes of the various radial modes. The relative amplitudes of these modes are determined by the manner in which the wave is excited, i.e., in this case by the geometry of the driving electrodes. The fields produced by the source of excitation can be analyzed into the radial normal modes of the waveguide, which form a complete orthogonal set. Such an analysis is difficult for the case of finite conductivity, but for the case of no damping a simple analysis can be made. We shall make the analysis for no damping in order to find the relative energies going into the various modes at the excitation end, and then somewhat arbitrarily we will apply the known damping to these modal amplitudes. In order to make the necessary expansion, we must know the boundary condition at the tube wall ($r = b$). This is the condition that determines the $k_{cn}$. It has been found experimentally that the radial wave current density $j_r$ is zero at the tube wall (see Radial Distributions of Wave Magnetic Field). Equation (13) then shows the boundary condition to be $J_1(k_{cn} b) = 0$. This leads to something of an enigma, since the method of inducing the wave requires a current to flow to the wall. The explanation seems to be that a high-density current from an external source can penetrate the insulating layer which otherwise exists between the plasma and the wall. Experimental evidence on this point is presented later in this paper. For the present analysis we approximate this state of affairs with the electrode structure shown in Fig. 2, taking at the end the limit as $c$ approaches $b$.

The assumed boundary condition at the insulator surface at $z = 0$ is that the axial current density $j_z$ is zero. The curl $b$ equation (Eq. (1) )
then shows that \( b_\theta(r, 0) \) is proportional to \( 1/r \). At the electrode surfaces at \( z = 0 \) the tangential electric field (\( E_r \)) since there is no \( E_\theta \) is zero. If we now assume zero damping, reference to Eq. (18) shows that the \( p_n \) are all equal. Then comparison of the equations for \( E_r \) and \( b_\theta \) (Eqs. (11) and (15)) shows that \( b_\theta \) is proportional to \( E_r \), and is thus zero at the electrode surfaces. We have then

\[
\begin{align*}
  b_\theta(r, 0) &= 0 \text{ for } a < r; \ c < r < b; \\
  &= \frac{\gamma}{r} \text{ for } a < r < c,
\end{align*}
\]

where \( \gamma \) is a constant.

This function is now equated to Eq. (11) at \( z = 0 \), giving

\[
b_\theta(r, 0) = \sum_{n=1}^{\infty} b_{\theta n} J_1(k_{cn} r),
\]

where the time dependence has been suppressed. To find the \( b_{\theta n} \), we multiply through on both sides by \( J_1(k_{cn} r) r \, dr \), integrate over the interval \( 0 < r < b \), and go to the limit as \( c \) approaches \( b \). Because of the orthogonality of the functions, only one term survives, and we obtain

\[
b_{\theta n} = -\frac{2\gamma}{b^2} \frac{J_0(k_{cn} b) - J_0(k_{cn} a)}{k_{cn} J_0^2(k_{cn} b)}.
\]

The ratio of wave energy in any one mode to total wave energy is now easily calculated to be

\[
\frac{W_n}{W_T} = \frac{2}{b^2 \ln b/a} \left[ \frac{J_0(k_{cn} b) - J_0(k_{cn} a)}{k_{cn} J_0(k_{cn} b)} \right]^2.
\]
In Table I we summarize some of the results of these calculations for conditions of this experiment. The second column shows the energy going into each of the first five modes, expressed as a percentage of total wave energy at the input end. The third column gives the calculated (amplitude) damping lengths for these modes, calculated from Eq. (17). The value of conductivity used was $3.13 \times 10^{-3} \text{ mho/meter}$, and was experimentally determined by measuring the attenuation of a wave that had traveled far enough so that only the lowest mode was present. Thus the damping length for the $n = 1$ mode is experimentally determined, and the others are calculated by using the same value of conductivity. Column four shows the energy left in each of these modes after the wave has made one transit through the tube, again expressed as a percentage of the total initial wave energy.

The lowest mode is excited most strongly (79% of the wave energy goes into this mode), and has considerably less attenuation than the higher modes. After the wave has made one transit through the tube, the energy in the second mode is 3.5% of the energy in the lowest mode, and the higher modes are present to a negligible extent.

EXPERIMENTAL METHOD AND RESULTS

Plasma Preparation

The geometry of the hydromagnetic waveguide is shown in Fig. 1. A copper cylinder 86.4 cm long and 14.6 in diameter is placed in a uniform axial magnetic field of 16.0 kilogauss and filled with hydrogen gas to a pressure of 100 microns. The ionizing current is supplied by a lumped-constant pulse line, so that the current of about 9000 amperes is nearly constant during the period of ionization. Conditions are such that the potential applied to the tube of about 4500 volts is also nearly constant, as shown in Fig. 3. The pulse line is connected between the electrode and the copper cylinder through a 1-ohm series resistance and an ignitron switching tube. When the current from this source is switched on, a local breakdown occurs in the gas at the end of the tube, after which a sharply defined ionizing wave travels through the gas. This wave shows similarities both to a switch-on shock wave and to a detonation wave, and is referred to as a switch-on ionization wave. The wave travels typically at 5 cm/µsec, and its front has been shown by magnetic probes and local wall-current probes to rise in about 0.5 µsec, corresponding to a thickness of the current layer of 2 to 3 cm. Note that since the current is forced by external circuitry to flow to the wall, the restriction mentioned in the theory section (\( j_r \) at the wall is zero) does not apply here. Figure 4 shows on the lower trace the voltage at an electrode (not shown in Fig. 1) placed coaxially in the end plate opposite the driving end and connected to the tube wall through a 0.3-ohm resistor. This voltage remains at zero during the time the wave is traveling through the
tube, then rises abruptly at the time the wave arrives. The progress of the wave down the tube can be observed by noting its time of arrival at each of five radial-current probes (Fig. 5) mounted in the cylinder wall. The radial current probe consists of a 0.25-inch-diameter section of the tube wall which is electrically isolated and connected to the adjacent cylinder through a 0.85-ohm resistance. The position of the wavefront as a function of time is shown in Fig. 6.

If the ionizing current continues to flow after the tube is filled with plasma, a sudden increase in the intensity of emission lines from materials associated with the pyrex end plates is observed spectroscopically. Therefore our practice is to short-circuit (crowbar) the ionizing currents as soon as the switch-on ionizing wave has filled the tube with plasma. This procedure is subject to one conspicuous exception, described later in connection with reflection from a copper end plate.

The ion density along a column of plasma 5 cm in diameter coaxial with the cylinder wall has been determined as a function of time.\(^9\) This is accomplished by measuring the first-order Stark broadening of the first three Balmer lines (H\(_\alpha\), H\(_\beta\), H\(_\gamma\)), using a monochromator to scan the lines. Cross-plots give the line shape as a function of time, and the curves are compared with the theory of Griem, Kolb, and Shen\(^{11}\) to find the ion densities. The result is that at the time the ionizing wave reaches the end of the tube, the ion density is \(>5\times10^{15}\) cm\(^{-3}\), corresponding to 80 to 100% ionization of the original neutral hydrogen gas present. The ion density decays by a factor of 2 in about 150 \(\mu\)sec. The ion density as a function of time is shown in Fig. 7. At the time the hydromagnetic wave experiments are performed, the ion density corresponds usually to \(>80\%) of the density of original neutral gas. The amount of neutral gas present at this time has not been measured. The
temperature of the plasma at this time has been estimated from observed Alfvén-wave damping to be at least $10^4 \, ^\circ\text{K}$.

**Generation of Waves**

A torsional hydromagnetic wave is induced in the plasma by discharging a 0.2-µf capacitor between the center electrode and the copper cylinder after the tube has been filled with plasma. For this work, the capacitor is critically damped so that only a single pulse of current flows. The current pulse is roughly a half sine wave, 0.8 µsec long. The resulting wave has been detected with small magnetic probes, which consist of a coil of 75 turns of wire on a 1-mm-diameter form. The coils are mounted inside re-entrant glass tubes fused onto the insulator at the receiving or driving end of the waveguide.

Our theoretical analysis postulates an azimuthally symmetrical wave propagation. The coaxial driving-electrode system has this property, and the copper cylinder was carefully aligned with the axial magnetic field, by a method which has been previously reported. The azimuthal symmetry was measured experimentally with four magnetic probes disposed 90 deg apart on same base circle. A random shot-to-shot variation of 10 to 20% was observed in individual probe signals, but the average of several shots gave azimuthal symmetry to within a few percent.

**Reflections**

An important check on the interpretation of these waves is provided by observation of reflections from various types of boundaries. These reflections have been observed from an insulating end plate, from a conducting end plate, and from a plasma–neutral gas interface. The phase relationships of reflected to incident wave fields at the boundary surface can be predicted easily by an examination of the wave fields, Eqs. (11) through (16). One can
measure the wave magnetic field \( b_\theta \) and the voltage \( V \) between a center coaxial electrode (of radius \( a \)) and the tube (of radius \( b \)), where

\[
V = \int_{a}^{b} E_r \, dr.
\]

We would thus like to analyze the phase relations to be expected for \( b_\theta \) and \( E_r \). For an insulating boundary at \( z = z_0 \), assuming no accumulation of charge, we have \( j_z(r, z_0) = 0 \). Then from Eq. (14) one can see that \( b_{\theta n} \) must reverse its algebraic sign in the reflected wave. Also \( p_n \) will always change sign in the reflected wave, since this wave is propagating in the negative direction. Then from Eq. (11) we can see that \( b_\theta \) will change phase on reflection, since it is proportional to \( b_{\theta n} \), which changes sign. From Eq. (15) we note that \( E_r \) is proportional to the product of \( b_{\theta n} \) and \( p_n \) (both of which change sign), and therefore \( E_r \) does not change phase on reflection.

For a conducting boundary at \( z = z_0 \) the condition is \( E_r (r, z_0) = 0 \). Then by a similar argument we find that \( E_r \) will change phase on reflection and that \( b_\theta \) will not.

Figure 8 shows \( V \) (top trace) and \( b_\theta \) (bottom trace) for the case in which a wave is reflected from a pyrex end plate at the far end of the tube. The voltage \( V \) is measured between the molybdenum electrode and the copper tube at the driving end of the tube (left-hand side of Fig. 1), and the wave magnetic field is measured with a magnetic probe 13 cm from the driving end (not shown in Fig. 1). The first signal is due to the initial wave, and then after a time delay corresponding to two transits of the tube with a velocity equal to the Alfvén velocity the signal from the reflected wave appears. The voltage (\( E_r \)) reflects in phase and the magnetic field (\( b_\theta \)) out of phase, as expected.
We next inserted a copper end plate in order to demonstrate reflections from a conducting boundary. The unexpected results shown in Fig. 9 were obtained; i.e., the phase relations are appropriate to a reflection from an insulating boundary. Apparently the plasma had become electrically isolated from the copper end plate, i.e., an insulating layer had formed at the wall. The source of this layer is unknown, but it seems most reasonable to believe that it is just due to a simultaneous drop in temperature and electron density in the immediate vicinity of the wall, which is in effect at low-temperature heat sink. If this hypothesis is correct one might reasonably expect that a high-density current flowing from the plasma to the copper plate would inhibit the formation of an insulating boundary layer and thus maintain electrical contact between plasma and copper. If the ionizing current from the pulse line is not crowbarred after the tube has been filled with plasma, this current continues to flow axially through the tube and into the copper plate. We therefore reflected a wave from the copper end plate while the ionizing current was flowing and obtained the results shown in Fig. 10. The electric field \( E_r \) now changes phase on reflection and the magnetic field \( B_\theta \) does not, as predicted for a conducting boundary. We shall return in the next section to the subject of the insulating layer surrounding a quiescent plasma.

Reflection of Alfvén waves from a plasma—neutral gas interface has also been observed. If the ionizing current is turned off (crowbarred) when the ionizing wave is part way down the tube, part of the tube is filled with a highly ionized plasma and the rest is filled with neutral gas (or at least gas with a very low degree of ionization). Under such conditions the Alfvén wave reflections shown in Fig. 11 were obtained, which have the expected phase relations for a nonconducting boundary. In the previous three cases, attenuation in the body of the plasma could explain the difference in incident and reflected wave amplitudes, but in this case the difference in amplitudes is too large and indicates a lossy reflection. The
ionizing current was stopped when the ionizing wave had just reached a radial current probe located 58 cm from the driving end of the tube. We wait 10 μsec for the ionizing current flow to cease and then induce the Alfvén wave. During this waiting time the interface probably moves on down the tube because of the plasma pressure. Using the Alfvén velocity measured under similar conditions when the tube was full of plasma, and the wave transit time measured from Fig. 11, one calculates that the reflection occurs from an interface located 68 cm from the driving end of the tube, in reasonable agreement with the estimate given above. Also, a magnetic probe near the receiving end of the tube (in the neutral gas) detects no wave signal. Thus reflection of Alfvén waves from a plasma—neutral gas boundary seems to be established. This phenomenon may be of particular interest in some astrophysical and geophysical problems.

Radial Distribution of Wave Magnetic Field

The radial distribution of the azimuthal magnetic field $b_\theta$ associated with the wave has been measured with magnetic probes. Six probes were used, disposed near the receiving end insulator at various radii. A typical probe container is shown at the right side of Fig. 1. The result of this measurement is displayed in Fig. 12. The upper solid curve is experimental data for a wave induced 20 μsec after the ionizing current was crowbarred. (The solid lower curve is discussed later.)

The observed $b_\theta$ becomes zero at the tube wall. Reference to Eqs. (11) and (13) shows that $b_\theta$ and $j_r$ have the same radial dependence. Therefore the observation indicates that no radial currents flow to the tube wall, as was previously noted in the section on theory. This observation was found to be true independently by looking for wall currents with the radial current probes. At first glance, the result is surprising, since the conductivity of the
copper is much higher than that of the plasma, and since the method of inducing the wave requires a current to flow to the wall. However, for the reasons discussed in the preceding section, the electrical conductivity in the plasma adjacent to the wall may be low, isolating the plasma from the wall.

The same distributions of $b_\theta$ were observed with either polarity of driving current, so that this effect does not seem to be associated with the well-known anode sheath which is sometimes observed in discharges where the current flow to a boundary surface is perpendicular to the static magnetic field.

The experimentally determined boundary condition, that radial current is zero at the wall, leads to the theoretical prediction for $b_\theta(r)$ which is shown as a dashed line in Fig. 12. This curve is calculated from the information given in Table I, and is normalized to the experimental data. A theoretical estimate of the wave magnetic field amplitude to be expected agreed with the experimental data within 40%. The zero of the Bessel function was taken to be 4 mm inside the physical wall, to better match the experimental data; this distance may be interpreted as roughly indicating the thickness of the nonconducting layer of gas.

The radial distribution of the wave magnetic field $b_\theta$ was also measured for a wave that had reflected from the receiving end of the tube and then from the driving end, i.e., the wave had made three transits of the tube. The result is displayed in Fig. 13. The dashed curve represents the lowest principal mode, and we observe that the wave which has made three transits of the tube is still predominantly the lowest-order mode.

The lower solid curve of Fig. 12 is the distribution of $b_\theta$ measured for a wave induced 90 $\mu$sec after the ionizing current was crowbarred. (For the previous discussion the waves were induced 20 $\mu$sec after crowbar.) In this case the peak of the distribution is shifted toward the axis of the tube.
This observation would be consistent with the assumption that the decaying plasma has a radial temperature gradient, with the warmest plasma (which would produce less wave attenuation) near the center of the tube.

ACKNOWLEDGMENTS

We wish to thank Dr. C. M. Van Atta and William R. Baker for interest in and encouragement of this work. Dr. William A. Newcomb made his unpublished analysis of hydromagnetic waveguides available to us. We wish to thank Dr. Wulf B. Kunkel, Dr. Theodore G. Northrop, and Dr. Klaus Halbach for commenting on the manuscript. Gerald V. Wilson, Louis A. Biagi, Peter R. Forman, and Pierre F. Pellissier gave us able assistance in the experimental work.

Fig. 3. Oscilloscope traces showing ionizing conditions. The top trace is voltage on the driving coaxial electrode at 2400 v/cm and the bottom trace is current from the pulse line at $10^4$ amp/cm. The horizontal scale is 10 μsec/cm. The current was crowbarred 22 μsec after the voltage was first applied. A single-pulse hydromagnetic wave was induced 48 μsec after the voltage was first applied.

Fig. 4. Oscilloscope traces showing arrival of ionization front. The top trace is the voltage on the driving coaxial electrode at 1000v/cm; the bottom trace is the voltage on the receiving coaxial electrode at 1000 v/cm. The horizontal scale is 10 μsec/cm. The axial magnetic field is 10 kG. The abrupt rise of the received voltage is evidence for a well-defined ionization front. Note that the information that the front has reached the load at the receiving end (0.33 ohm, not shown in Fig. 1) requires one Alfvén transit time (2.8 μsec) to reach the driving end, at which time the driving voltage decreases somewhat.

Fig. 5. Geometry of the radial-current probe. The 1/4-in.-diameter button is connected to the adjacent wall through six parallel 5-ohm resistors. The maximum voltage drop is less than 1 v.

Fig. 6. Position of the ionization front vs time, as measured with radial current probes. The axial magnetic field was 16.0 kG, which resulted in a shorter transit time for the front than is the case shown in Fig. 3.
Fig. 7. The observed time dependence of the ion density. Errors (not shown) in the experimental points are estimated to be $\pm 1.0 \times 10^{15}$ cm$^{-3}$ late in the decay period. The solid line is a least-squares fit, assuming the decay rate to be proportional to the square of the ion density. The dashed line assumes an exponential decay.

Fig. 8. Oscillogram showing reflection from a Pyrex end plate. Upper trace is the voltage measured at the driving end of the tube between cylinder and coaxial electrode at 100 v/cm. Lower trace is azimuthal magnetic field, measured by a probe 13 cm from driving end with a sensitivity of 34 gauss/cm. The sweep speed is 1 $\mu$sec/cm. The first pulse is the induced wave, and the first reflection occurs about 3.5 $\mu$sec later, on the voltage trace, corresponding to two transits through the tube at the Alfvén speed. The voltage reflects in phase, the magnetic field out of phase, in accord with theory for a nonconducting boundary.

Fig. 9. Oscillogram showing reflection from a copper plate 30 $\mu$sec after the plasma has started to decay. Traces are as in Fig. 8, with upper trace at 250 v/cm and lower trace at 50 gauss/cm. The phase of the reflected fields is the same as for a nonconducting boundary, indicating that the copper wall is isolated from the plasma.

Fig. 10. Oscillogram showing reflection from a copper plate with ionizing current still flowing to the plate. Traces are as in Fig. 8, with upper trace at 250 v/cm and lower trace at 68 gauss/cm. The electric field has reflected out of phase and the magnetic field in phase, in agreement with theory for a conducting boundary.

Fig. 11. Oscillogram showing reflection from an interface between plasma and neutral gas. Upper trace is voltage on end electrode at 250 v/cm and lower trace is magnetic field at 70 gauss/cm. The phases indicate
a nonconducting boundary at reflection. The small amplitude of the reflected signal indicates a lossy reflection.

**Fig. 12.** The radial distribution of the wave magnetic field $b_\theta$, measured near the receiving end of the tube after the wave has made one transit ($Z = 74$ cm). The upper dashed curve is proportional to the theoretical distribution calculated from Table I for a wave induced 20 $\mu$sec after crowbar. The upper solid curve is the measured distribution for a wave induced 20 $\mu$sec after crowbar, and the lower solid curve is the measured distribution for a wave induced 90 $\mu$sec after crowbar.

**Fig. 13.** The radial distribution of the wave magnetic field $b_\theta$, measured near the receiving end of the tube after the wave has made three transits of the tube (i.e., two reflections; $Z = 247$ cm); 20 $\mu$sec after crowbar. The dashed curve is proportional to the theoretical distribution for the lowest mode ($J_1(k_{cn} r)$).
