An extension of the theory of Ornstein (1906) and Nye (1967) for the drag force on circular wires and other solid bodies creeping through ice by means of pressure-melting and regelation is provided. Nye’s theory leads to a form of Stokes law, with rates controlled by heat conduction and lubrication flow in a thin water layer between ice and solid body. New analytical solutions are given for the corresponding drag force and torque on elliptical cylinders and spheroids for the special case of thermally thin water layers and for certain special forms of uncoupled translation and rotation that allow for single-harmonic temperature fields. The present results differ from those proposed by Nye for general body shapes in the limit of negligible thermal resistance of the water layer. Also, the present results for the drag force on elliptic cylinders do not agree with the formulae derived by Tyvand and Bejan (1992) for small ellipticity. A brief review is given for various effects that might account for certain departures of the Nye theory from experiment on circular wires, in the hope that the present results may suggest simpler experiments aimed at systematic modification of the theory to account for such anomalies. © 2014 American Institute of Chemical Engineers AIChE J, 00: 000–000, 2014

Keywords: pressure melting, ice regelation, hydrodynamic lubrication, harmonic functions, glaciers, basal melting

Introduction

The works of the brothers Thomson1–3 and Michael Faraday4,5 mark the beginnings of a sustained scientific fascination with “regelation,” the pressure-induced thawing and refreezing of ice at solid boundaries. The Thompson theory of pressure melting has been invoked to explain phenomena as diverse as the mobility of glaciers and the reduction of sliding friction on ice skates. It is also the subject of well-known classroom experiment involving the passage of a solid wire through a block of ice, leaving scarcely a trace.* Following a much earlier analysis of Ornstein6 for the passage of a circular wire through ice, Nye7 gave an insightful mathematical theory for the translational drag force on circular cylinders and certain other idealized solid bodies. According to these theories, the speed of movement is linear in the applied force and controlled by a lubrication-type flow around the body in a thin interfacial water layer, combined with conduction of heat through wire, ice, and water. Thus, one encounters an interesting generalization of the classical Stefan problem, in which the usual heat conduction is now coupled with viscous flow and pressure-induced change of melting temperature. Despite this complexity, the remarkable works of Ornstein and Nye demonstrate the existence of simple analytical solutions based on the angular symmetry of the associated harmonic temperature and pressure fields. Their work provides considerable impetus to the present study, which demonstrates that one can still obtain exact analytical solutions for bodies with more complex symmetry, provided the thermal resistance of the melt layer can be neglected.

As a cautionary note on the underlying model, we recall that numerous careful experiments, several cited by Nye,7 show only limited agreement with theory. This state of affairs has spurred subsequent theoretical speculation and further experiment, briefly summarized here.

In conjunction with Nye’s work, Frank8 predicts an instability of the freezing front behind the wire as a possible explanation of irregular ice–water structures seen in its wake. Known more generally as “Mullins–Sekerka” instability,9,10 it is now recognized as responsible for “mushy zones,” with interesting theology and mechanics.11 Although such irregularity would vitiate the Nye model, it is not clear that it could explain the general reduction in speed observed in most experiments.

Drake and Shreve12 conducted further careful experiments, also providing a critical historical survey of theory and experiment on round wires and offering various explanations for the failure of the Nye theory. Their extensive analysis of experimental data reveals a nonlinear drag at low force, with speeds much less than those predicted by the Nye theory, followed by a transition at large forces to speeds closer to theory. This anomalous behavior is generally much more pronounced for high-conductivity wires.

Prior to the transition mentioned above, Drake and Shreve12 point up the existence of a trace or “wake” of liquid and vapor bubbles behind the wire, which they attribute to the freezing-front instability, without considering the possible cavitation in lubricating layers discussed elsewhere.13–15 At any rate, their general conclusion is that, depending on the thermal conductivity of the wires, the departures from Nye’s
theory are mainly due to freezing-point depression by impurities dissolved in the ice, or by supercooling associated with finite rates of freezing, as suggested earlier by Nye. The elementary mathematical analysis of these effects by Drake and Shreve leads one to hope that simple modifications of Nye’s theory may be sufficient to explain discrepancies with experiment.

To finish this cursory review, some mention should be made of some other possible implications of microscopically thin water layers, such as frictional melting and “premelting.” As suggested by the experiments of Evans et al., tribological effects arising from surface roughness, solid friction, and energy dissipation could affect the above regulation experiments, although they are doubtless much more important in high-speed processes such as ice skating. Also, we recall the possible existence of microscopic “premelting” water layers on solid ice, anticipated by Faraday as part of his critique the Thomson theory of pressure-melting, and now believed to involve Van-der-Waals “disjoining forces.” Recent numerical simulations indicate that hydrophobic surface forces act to retard the motion of nanowires through ice. Although such effects should be much less important for larger bodies, one cannot rule out a well-known breakdown of lubricating films at low velocities with transition to the so-called “boundary-lubrication” regime involving virtual solid–solid contact. Moreover, the inevitable lateral drainage in the typical moving-wire experiment could also lead to greatly reduced melt-layer thickness at low speeds.

Setting aside complications arising from the above effects, the following analysis aims to systematize the theory of Nye and to derive analytical solutions for various body shapes undergoing rotation as well as translation. Although the set of analytical solutions is limited, the present formulation could facilitate the numerical solution of more complex body shapes and motions, and it may also suggest alternative experimental configurations for the study of regulation.

It should be noted that a previous work on the translation of slightly elliptical cylinders already suggests the possible importance of variable melt-film thickness on lubrication pressure and melting temperature. This is borne out by the present analysis for arbitrary ellipticity, which provides a somewhat different result for the limit of small ellipticity.

The following analysis will also treat the rotation of elliptical cylinders and ellipsoids in a stationary body of ice, which leads to a doubling of the number of high and low pressure zones and a corresponding doubling of melting and regulation zones. One can anticipate further spatial multiplicity in the case of more complex bodies such as serrated cylinders, as the analog of Nye’s wavy-surface model of glacial sliding over rough terrain. Although we shall not consider it here, a small-amplitude approximation like that of Nye could no doubt be used to treat the combined translation and rotation of any slightly deformed cylinder or sphere.

A major goal of the present work is to reformulate the Ornstein-Nye model in a general form that should be comprehensible to workers in the field of transport phenomena. Not only does this serve to reveal the underlying regimes and approximations in terms of relevant nondimensional parameters, but it also provides a starting point for numerical simulations that are unconstrained by certain approximations used in the present work. Furthermore, the improved formulation of the problem could facilitate the systematic analysis of effects not included in the model, such as freezing front instability and cavitation in the melt layer, which are treated in a somewhat ad hoc fashion by previous workers. With this in mind, the exact solutions presented below for thermally thin melt layers may be viewed as points of reference for more comprehensive models.

**Mathematical Model and Analysis**

As a prelude to the analysis to follow, we recall the key features of Nye’s model of regulation, in which a rigid thermally conductive body B undergoes a creeping motion within a stationery unbounded body of ice I, also regarded as a rigid heat conductor. Temperature and velocity fields are assumed time-independent in a frame moving with the body, as illustrated schematically in Figure 1, where the ice has velocity $\mathbf{u}(x) = \mathbf{z} + \omega \times \mathbf{x}$.

$$
\mathbf{u}(x) = \mathbf{z} + \omega \times \mathbf{x}
$$

(1)

where $\mathbf{z}, \omega$ are constant vectors representing translation and rotation of I relative to B, respectively. The relative motion (1) is accommodated by melting, regulation, and flow in a thin water film W separating B from I. Following Nye, we neglect the effects of shear stress, anisotropy of ice, and a freezing-front instability discussed below.

According to the analysis of Nye, the variation in melting temperature $T_M$ is induced by a lubrication-type pressure variation in the water layer, with

$$
T_M - T_0 = -\frac{2a^2\rho_0}{\delta \rho_w} U
$$

where $T_0$ is the melting temperature at ambient pressure $p_0$, $\delta$ is a characteristic layer thickness, $a$ an characteristic dimension of the solid body, $U$ a characteristic relative velocity between solid body and ice, $\rho_A$ the density of body “A,” $\mu$ water viscosity, and $\gamma$ the pressure-melting coefficient. The factor of 12 has been included in (2) for later notational convenience.

With the balance of heat between melting and regulation zones governed by conduction, we have

$$
\frac{k(T_M - T_0)}{a} \sim \lambda \rho_1 U
$$

where $\lambda$ is the specific heat of fusion of ice (energy per unit mass) and $k$ a characteristic thermal conductivity, one obtains as characteristic length ratio or Nye number

$$
\frac{\alpha}{\delta} = \left( \frac{a^2 \rho_w \lambda}{12 \mu \gamma k} \right)^{1/3} = \left( \frac{\rho_1 (a \rho_w \lambda)^2}{12 \mu (\rho_w - \rho_1) k T_0} \right)^{1/3}
$$

Figure 1. Schematic illustration of rigid ice mass I moving relative to rigid body B.

---

1Nye uses thermal resistivity, the inverse of the thermal conductivity used here, and a volumetric latent heat given by $\rho_1 \lambda$ in the present notation.
With $T$ denoting absolute temperature, the last expression follows from the formula for $\gamma$ given by linearization of the Clapeyron equation

$$\frac{d}{dp} \ln T_M = -\frac{(\rho_w - \rho_l)}{\rho_l p_w \lambda}$$ (5)

and it represents a more detailed form than given by Nye.\(^7\)

With values representative of water at 0°C and with $a \approx 1$ mm, (4) gives $\mathbb{N} \approx 10^4$ and, hence, $\delta \approx 1$ mm. In the following, we take $k = k_B$ in the definition (4), but even for larger values of $k$ representative of metals such as copper our estimate of $\mathbb{N}$ is decreased at most by a factor of 10. Therefore, the water layer may generally be considered geometrically thin, in contrast to the exaggerated scale shown in Figure 1.

In addition to its hydraulic role, the layer constitutes a thermal resistance in series with the resistance presented by body $B$\(^7\) and with relative magnitudes

$$\epsilon := \frac{k_B \delta}{k_w a} \equiv \frac{k_B}{\mathbb{N} k_w} \sim \frac{k_B}{\mathbb{N} k_l}$$ (6)

This represents relative thermal resistance or characteristic “thermal thickness” of the water layer, which obviously can become large for $k_B \gg k_w$.

As indicated by Ref. 7, the characteristic force $f$ on the body $B$ is determined by hydrodynamic lubrication pressures, yielding a highly magnified Stokes-law drag

$$f \sim \mathbb{N}^3 \mu U a$$ (7)

With the above parameter values, this gives velocities $U$ of a few mm/h for forces $f \approx 1$ N. Such velocities result in exceedingly small thermal Péclet numbers, essentially the same for the water layer as for the external ice flow, and represent Nye’s criterion for neglect of convective heat transfer. Moreover, the shear stress arising from shearing of the water layer engenders forces that are $O(\mathbb{N}^{-1})$ times that in (7) and hence negligible for large $\mathbb{N}$, as also recognized by Nye.

**Basic equations and parameters**

Following,\(^7\) we treat the water layer as a geometrically and hydraulically thin region $W$ lying adjacent to $\partial B$ and having a thermal conducance $k_w/\delta$ in a direction normal to $W$ and a hydraulic conducance in a direction tangent to $W$ given by hydrodynamic-lubrication theory. Then, with constant properties in $B$, $W$, $I$, the governing equations for the temperature field $\Theta = T - T_0$ and the lubrication pressure $P = p - p_0$ become

$$\nabla^2 \Theta(x) = 0, \quad x \in B, I, \text{ with } \Theta \rightarrow 0 \text{ for } |x| \rightarrow \infty$$ (8)

$$-k_l \frac{\partial \Theta}{\partial n}(x+) - \rho_l \lambda U_n(x) = -k_B \frac{\partial \Theta}{\partial n}(x-)$$ (9)

$$= \frac{k_w}{\delta^3} (\Theta(x-) - \Theta(x+)), \Theta(x+) = -\gamma P(x), \quad x \in W$$

$$\mathbf{V}_W \cdot \left( \frac{1}{12 \mu} \mathbf{V}_W P(x) \right) = \frac{1}{2} \mathbf{V}_W \cdot (t \mathbf{u}_W) + \frac{\rho_l}{\rho_w} U_n(x), \quad x \in W$$ (10)

where

$$U_n(x) = \mathbf{u} \cdot \mathbf{n}, \frac{\partial}{\partial n} = \mathbf{n} \cdot \nabla, \mathbf{u}_W = \mathbf{v} - \mathbf{n} \frac{\partial}{\partial n}$$ (11)

$\mathbf{u}$ is given by (1), $x^\pm$ denoting limiting values as $x \to W^\pm$, representing the outside and inside of $W$, respectively, and $\mathbf{n}$ denotes the unit outer normal to $B$. Subscripts $W$ denote projections onto $W$, and the lubrication Eq. 10 is standard.\(^2\)

The set (8)–(10) represents the aforementioned generalization of the classical Stefan problem\(^10\) involving the coupling of a Neumann problem in $B$ to a Robin problem in $I$. These equations suffice presumably to determine $\Theta(x), P(x)$, and $t(x)$ given $\mathbf{u}(x)$. The first equation of the thermal balance (9) and the right-hand side of the mass balance (10) show that melting, regelation, and water flow can be regarded as kinematically controlled through the specification of $U_n$. Accordingly, the resultant vector force and torque on $B$ are determined by the orientation of $B$ and the motion (1). As discussed below, Nye’s solution for the translation of circular cylinders or spheres yields a constant film thickness $t$ given by the positive root of a quartic polynomial.

Based on characteristic velocity $U$ and body dimension $a$, we introduce nondimensional quantities

$$\hat{x} = \frac{x}{a}, \quad \hat{V} = a V, \quad \hat{u} = \frac{u}{U}, \quad \hat{t} = \frac{t}{\delta}, \quad \hat{k}_l = \frac{k_l}{k_B}, \quad \hat{k}_w = \frac{k_w}{k_B},$$

$$\hat{\Theta} = \frac{k_B \Theta}{a \rho_l \lambda U}, \quad \hat{\Theta}_M = -\frac{k_w P}{a \rho_l \lambda U}, \quad \hat{f} = \frac{f}{6 \pi \mu a U}, \quad \hat{\tau} = \frac{\tau}{6 \pi \mu a^2 U}$$ (13)

where $\delta$ is given by (4) with $k = k_B$, and the force and torque have been normalized by Stokes-law force on a sphere of radius $a$. Thus, (8)–(12) take on the form

$$\nabla^2 \hat{\Theta}(x) = 0, \quad x \in B, I, \text{ with } \hat{\Theta} \rightarrow 0 \text{ for } |x| \rightarrow \infty$$ (14)

$$-\hat{k}_l \frac{\partial \hat{\Theta}}{\partial \hat{n}}(x+) - \hat{\rho}_l \hat{\lambda} \hat{U}_n(x) = -\hat{k}_B \frac{\partial \hat{\Theta}}{\partial \hat{n}}(x-)$$ (15)

$$= \frac{1}{\hat{\omega}} [\Theta(x-) - \Theta(x+) ], \quad \Theta(x+) = -\hat{\gamma} \hat{P}(x), \quad x \in W$$

$$\hat{f} = \frac{2 \hat{\omega}^3}{\pi} \int_W \hat{\Theta}_M n dA, \quad \hat{\tau} = \frac{2 \hat{\omega}^3}{\pi} \int_W \hat{\Theta}_M n \times x dA$$ (17)

where carets have now been dropped, with (11) remaining unaltered in form. In the case of an infinite cylinder moving normal to its axis, the area element $dA$ is to be interpreted as circumferential arc length, so that (17) gives force and torque per unit length of cylinder.

On the right-hand sides of the equations given in (16) and (17), as in the following analysis, terms in

$$\frac{P_w - P_l}{\rho_w}, \quad \text{and } \mathbb{N}^{-1} \mathbf{V}_W \cdot (t \mathbf{u})$$ (18)

are neglected. The parameter $\epsilon$ is defined by (6), and all variables and gradients in (14)–(16) are provisionally $O(1)$ in magnitude. Apart from the Clapeyron equation 5, we ignore density differences between water and ice (taking Nye’s factor $f$ equal to unity).

Comments on Nye’s Findings

To relate to Nye,\(^7\) we note that his regimes “(1 A), (2 A), . . ., (1 B), . . .”, are represented by pairs selected from the rows in Table 1, where the first row represents water layers ranging from the thermally thin (1) to the thermally thick (3), whereas the second represents relative resistances of body to ice. The thermally thin water layer \( \epsilon = 0 \) represents the main focus of the present investigation, in which we eventually replace the last two equalities in (15) by

\[
\Theta(x) = \Theta(x) = \Theta_M(x), \quad x \in W
\]  

(19)

According to Nye\(^7\) (p. 1259), the nondimensional drag force on a translating cylinder with \( \epsilon = 0 \) is given, in the present notation, by the simple form

\[
f = \frac{2V}{\pi \alpha} \frac{h_1}{1 + k_1}
\]

(20)

where \( V \) is cylinder volume. However, if applied to general cylinders, the implied independence of body shape is at odds with the anisotropic drag law found below.

When \( k_1 \) is replaced by \( 2k_1 \) and \( V = 4\pi \alpha^3/3 \), (20) one obtains Nye’s exact result for the force on spheres with \( \epsilon = 0 \), cited below in (58). Setting \( k_1 = 0 \) in (20) also yields Nye’s proposed result for general bodies in Case (1 A), with force independent of body shape. Once again, this is at odds with the analysis of three-dimensional (3-D) bodies presented below. As will become evident, the difference between the findings of Nye and the present work can be traced to the dependence of thermal and hydraulic resistance on body shape, as represented by variations in surface-normal metrical properties.

**Bulk and surface flow potentials.** The following analysis rests heavily on harmonic decompositions, about which a few remarks are in order.

Regarding \( U_n \) as given by a potential flow\(^4\) with velocity field \( v \)

\[
v = -\nabla \Psi, \quad x \in I, \quad U_n = v \cdot n = -\frac{\partial \Psi}{\partial n}, \quad \Psi = \Theta_M, \quad x \in W
\]

(21)

one sees that (16) is a generalization of the equations proposed to describe potential flow in the presence of highly conductive surface layers\(^5\) (Eqs. 2.16–2.18), with \( t^3 \) representing a variable tangential conductance on \( W \).

As it will be useful for what follows, we set down here a slight generalization of the results derived in the appendix of Miloh and Benveniste\(^25\) for the projection of vectorial divergence from a (Euclidean) space of dimension \( m > 1 \) onto a subspace \( W \) of dimension \( m - 1 \).

In terms of orthogonal curvilinear coordinates, say, \( x_i \), with metric coefficients \( h_i, i = 1, \ldots, m \), we recall that first that

\[
\mathbf{v} \cdot \mathbf{v} = \frac{1}{\Pi m} \sum_{i=1}^{m} \frac{\partial}{\partial h_i}\left( \frac{\Pi m}{h_i} \right), \quad \Pi m = \prod_{i=1}^{m} h_i
\]

Then, assuming that \( W \) is represented by the surface \( x_m = x_W \) = constant, and integrating (22) across a vanishingly thin region adjacent to \( W \), with \( ds_m = h_m dx_m \) and \( t = \int ds_m \), we obtain

\[
\int_0^1 \left( \mathbf{v} \cdot \mathbf{v} \right) ds_m = \int_0^1 \left( [v_m]_W + \mathbf{v}_W \right) \cdot t(v)_W, \quad \langle v_i \rangle_W = \frac{1}{t} \int_0^1 v_i ds_m, \quad i = 1, \ldots, m - 1
\]

(23)

where \( [v_m]_W = \mathbf{v} \cdot n \) denotes the normal jump across \( W \), and where the surface divergence \( \mathbf{v}_W \cdot \mathbf{n} \) on \( W \) is given by (22), with \( \{v, m\} \) replaced by \( \{w, m - 1\} \) and with \( h_1 \) evaluated at \( x_m = x_W \). Hence, the definition of \( \mathbf{v}_W \cdot \mathbf{n} \) follows on replacement of \( w_1 \) by \((\kappa/h_1)\partial/\partial x_1 \), where \( \kappa \) is any scalar field on \( W \).

Another virtue of the representation (21) is that it allows us to express (15) in the form

\[
-k_i \partial_i \Theta(x) - \partial_m \Psi(x) = \partial_m \Theta(x) = \frac{h_W}{h t} \left[ (\Theta(x) - \Theta(x)) \right]
\]

\[
\Theta(x) = \Theta_M(x), \quad x \in W, \quad \partial_m = \partial/\partial x_m, \quad h_W = h_m(x), \quad x \in W
\]

(24)

With Nye’s assumption of separability, \( \Theta \) and \( \Psi \) have the form \( \Theta_M(x_1, x_2)F(x_3) \), at least locally, and it is evident that one must have \( t \propto h_W(x_1, x_2) \), in order that each of member of these equations involve the same function \( \Theta_M(x_1, x_2) \). However, this special form for \( t \) generally does not allow for a solution \( \Theta_M \) to (16) in terms of surface harmonics, as required for compatibility with (21).

In the case of a thermally thin water layer \( \epsilon = 0 \), (19) applies, which leads to an analytic expression for \( t \) in terms of surface-normal metric and to solutions \( \Theta_M \) in terms of surface harmonics. This can be formulated generally in any dimension \( m \) by first noting that Laplace’s equation for \( \Psi = \Theta_M(x_1, \ldots, x_{m-1})F(x_m) \), with \( F(x_m) \equiv 1 \), becomes

\[
\sum_{i=1}^{m-1} \frac{1}{\Pi m} \frac{\partial}{\partial h_i}\left( \frac{h_W}{h_i} \right) \frac{\partial \Theta_W}{\partial h_i} = \frac{\Theta_W}{h_W} \frac{d}{dx_m} \left( f_m \frac{d}{dx_m} \right) = 0, \quad \text{for} \quad x_m = x_W
\]

(25)

provided \( \Pi m/(h_m^{m-1}) \) is independent of \( x_m \), where the function \( f_m = f_m(x_m) \) is the last one of the \( f_i, i = 1, \ldots, m \) arising from the standard separability.\(^26\) Hence, by choosing \( t^3 = t^3 h_W \), where \( t^3 \) is a suitably chosen constant, and by taking \( h_W \mathbf{U} = -\Theta_M \mathbf{d}F/\mathbf{dx}_m |_{x_m = x_W} \), we can reduce (25) to the form (16). No attempt is made here to prove that this sufficient condition is necessary. This technique, illustrated by the special cases of elliptic cylinders and spheroids considered below, may also be useful for more general body shapes.

**Planar Problems**

Before assuming \( \epsilon = 0 \), we first consider motions of cylinders in the plane, with forces and torques in (12) representing the action on unit length of the cylinder.

\(^{25}\)Miloh and Benveniste (1987). (Ch. VI), a flow whose enthalpy flux \( q_1/(-4k_1) \) has zero divergence and the same normal component on \( W \) as the actual one \( -q_1/(u - 4k_1) \).

Circular cylinders

Referred to cylindrical polar coordinates \( r, \theta \), the case of a circular cylinder \( r = 1 \) translating in a fixed direction (x) normal to its axis is covered by (1), with

\[
\omega \equiv 0, \quad \mathbf{a} = \cos \phi \mathbf{e}_r + \sin \phi \mathbf{e}_\theta, \quad \mathbf{n} = \mathbf{e}_r, \quad U_n = -\cos \phi \frac{\partial}{\partial r} = \partial_r |_{r=1}
\] (26)

where \( \mathbf{e}_r, \mathbf{e}_\theta \) denote unit basis vectors. Then, with \( \partial_r = \partial / \partial x \) for any coordinate \( x \), we may write

\[
\nabla^2 = \frac{1}{r} \partial_r (r \partial_r) + \frac{1}{r^2} \nabla^2 _{\mathbf{e}_r}, \quad \nabla^2 _{\mathbf{e}_\theta} = \partial^2 _{\mathbf{e}_\theta}
\] (27)

As shown first by Refs. 5,6\(^6\) and later by Ref. 7, at least one solution to (14)–(16) has \( t = \text{constant} \) and the remaining independent variables given by harmonic forms \( R(r) \cos \phi \), with \( R = A, B, C \), respectively, for \( \Theta_M(x) \), \( x \in W \), and \( \Theta(x) \), \( x \in B, I \). Substitution into (14)–(16) leads to simultaneous equations for \( A, B, C, \phi, t \), and thence to the quartic equation for \( t \)

\[
t^3 = \frac{1}{1 + \epsilon t} + k_t
\] (28)

where \( t, k_t \) refer to the quantities distinguished by catars in (13). We recall that Ref. 7 expresses this quartic in terms of \( \epsilon t \) and neglects a linear term in \( \epsilon t \) depending on the single parameter \( \epsilon^2 (1 + k_t) \). Nye’s insightful treatment of (15) as thermal resistances \( B \) plus \( W \) in parallel with resistance \( I \) yields a straight-forward determination of the constants \( A, B, C \) in terms of \( t \). The force \( f \) in (17) is given in terms of \( A \), and the reader is referred to Ref. 7 for the details.

General cylinders

By means of complex variables

\[
z = x + iy = re^{i \phi}, \quad \mathbb{z} = \zeta(z) = \xi + \eta \mathbb{e}^{i \phi}\n\] (29)

the (Riemann) circle theorem allows us to transform a sufficiently smooth boundary \( r = \gamma_W(\phi) \) of a simply connected region in the \( \mathbb{z} \)-plane into the unit circle \( g=1, 0 \leq \phi < 2\pi \), in the \( z \)-plane, by means of a suitable conformal map \( \zeta(z) \). To transform the basic equations to the complex plane, we make use of the well-known map between (contravariant) vector components and complex numbers

\[
\mathbf{u} = u_x \mathbf{e}_x + u_y \mathbf{e}_y \rightarrow u = u_x + i u_y
\] (30)

with

\[
\mathbf{u} \cdot \mathbf{v} = u_x v_x + u_y v_y, \quad \mathbf{v} = v_x \mathbf{e}_x + v_y \mathbf{e}_y
\] (31)

and

\[
\nabla \cdot s = \partial_r s + i \partial_\theta s, \quad \nabla \cdot \nabla \cdot s = \nabla \cdot (\mathbf{v} \cdot \mathbf{v}) \cdot s, \quad \mathbf{v} = v_x \mathbf{e}_x + v_y \mathbf{e}_y
\] (32)

with overbar denoting complex conjugate. If \( u \) represents a contravariant form, then \( \bar{u} \) represents the covariant form, and vice versa, so that the invariance of scalar product and covariance of vector cross product is manifest in (31).

In the following \( \Re \) and \( \Im \) denote real and imaginary parts, respectively. With \( \zeta, \eta \) representing orthogonal curvilinear coordinates in the \( \mathbb{z} \)-plane, a locally orthogonal transformation of physical-space vectors is defined by

\[
u = u_x (u_x e_x + u_y e_y) = e^* u_x, \quad \text{with} \quad \sigma = \arg e^* = \frac{d \zeta}{dz} = \frac{1}{\zeta}
\] (33)

where the quantities \( h \) are metrical coefficients. Then, the complex representation of (1) is

\[
u = u_x e_x + u_y e_y = e^* u_x, \quad \text{with} \quad \mathbf{v} = v_x \mathbf{e}_x + v_y \mathbf{e}_y
\] (34)

with

\[
u = \bar{u}_x \mathbf{e}_x + \bar{u}_y \mathbf{e}_y, \quad \mathbf{v} = v_x \mathbf{e}_x + v_y \mathbf{e}_y
\] (35)

By means of (23), (15), and (16) assume the coordinate-dependent form

\[
-k_t \partial_\phi \Theta = -h_W U_n = -k_t \partial_\phi \Theta + \partial_\phi \Psi
\] (36)

where

\[
\Theta_M(\phi), \quad t = t(\phi), \quad h_W = h_W(\phi) = h_c(\phi, \eta)|_{\eta=1}, \quad \partial_\phi = \frac{d}{d\phi}
\] (37)

with subscripts \( \pm \) referring to limits at \( \phi = 1 \). The circular cylinder discussed above has of course \( \zeta \equiv \zeta \), with \( h_W \equiv 1 \). For noncircular cylinders the distortion of coordinates, with by \( h_W(\phi) \neq 1 \), rules out solutions with constant \( t \) of the type considered by Nye.

By means of (30)–(35), the nondimensional force and torque are given, respectively, by

\[
f = f_x + i f_y = \frac{2 \pi}{\pi} \int_W \Theta_M \nabla \cdot (\mathbf{u} \times \mathbf{v}) \cdot s ds = \frac{2 \pi}{\pi} \int_0^{2\pi} \Theta_M e^{i \sigma \omega} r_W d\phi
\] (38)

\[
\tau = 2 \frac{\pi}{\pi} \int_W \Theta_M \Im \nabla \cdot (\mathbf{u} \times \mathbf{v}) \cdot s ds = \frac{2 \pi}{\pi} \int_0^{2\pi} \Theta_M (\phi) \sin (\sigma_W(\phi) - \sigma_W(\phi)) r_W h_W d\phi
\] (39)

The harmonic function \( \Theta \) can be expressed generally as a linear combination of \( \mathbb{g}^* \cos \sigma_W \eta \) and \( \mathbb{g}^* \sin \sigma_W \eta \), with \( n = \mp 1, \pm 2, \ldots \), for \( \eta \geq 1 \), respectively, whereas the periodic functions \( U_n, h_W, \Theta_M, t \) can be expressed as trigonometric series in \( \cos \sigma_W \eta \) and \( \sin \sigma_W \eta \). Without pursuing the details, it is plausible that the relations (37) and (38) would suffice to determine the unknown coefficients in the trigonometric series for \( \Theta, \Theta_M, t \), given the coefficients in the series for \( U_n, h_W \), as dictated by the map \( \zeta(z) \) and the motion (1). Although this is worthy of further investigation, attention will be focused in the present article on analytic solutions for the limit \( \epsilon = 0 \).
Solutions for $\epsilon=0$

Because of the $\varphi$-dependent scale factor $h_w$, it is evident from (37) to (38) that there exists no solution having constant $t$. Conversely, when $\epsilon=0$ we can replace (37) by

$$-k_i\partial_i\Theta_+ - h_w U_+ = -k_i\partial_i\Theta_- - \partial_\varphi \Psi_+ = -\partial_\varphi \Theta_- \quad \text{and} \quad \Theta_- = \Theta_+ = \Theta_M$$

and, as anticipated above, we can obtain a simple class of analytical solutions with

$$t^3 = t^3_0 h_w(\varphi), \quad t_0 = \text{const.} \quad (43)$$

Then, given the harmonic forms $\Theta(\varphi, \psi) = F(\varphi) \Theta_M(\varphi)$ and $\Psi(\varphi) = S(\varphi) \Theta_M(\varphi)$, the relations (38) and (42) can be reduced to

$$\Theta_M' + n^2 \Theta_M = 0, \quad \Theta_M = -\frac{h_w U_+}{M}, \quad F_+ = F_- = 1 \quad \text{at} \varphi = 1,$$

and $t_0^3 = \frac{M}{n^2}$, where $M = F_- - k_i F_+ = (1 + k_i)n$

and where, as above, subscripts $\pm$ refer to limits $\varphi \to 1 \pm \delta$. The requirement that $\Theta(\varphi)$ be periodic and, hence, that $n$ be an integer, uniquely determines $t_0$ once $n$ is specified. However, it remains to specify $n$ and $h_w$, and to make this more evident we consider the special case of elliptic cylinders.

Ellipses

The special case of an elliptic cylinder $B$ having principal semi-axes $a \geq b$ is covered by

$$\dot{z} = \dot{x} + i\dot{y} = \frac{1}{2} \left( \xi + \xi^{-1} \right), \quad \dot{\xi} = \frac{z}{r_0}, \quad \xi = \frac{z}{r_0} = \exp(\chi + i\varphi)$$

with

$$\frac{\dot{\xi}^2}{\cosh^2 \chi} + \frac{\dot{\varphi}^2}{\sinh^2 \chi} = 1, \quad \frac{\dot{\varphi}}{\sin \varphi} = \frac{\dot{\varphi}}{\sin \varphi} = 1 \quad (46)$$

with $\chi = \ln \dot{\varphi}, \dot{\varphi} = |\dot{\varphi}|, \dot{\varphi} = (1 - \beta^2)/(1 + \beta^2), \quad r_0^2 = 2(1 - \beta^2)/\beta^2, \quad \beta = b/a$

(47)

The surface $W = \partial B$ is defined by $\varphi = 1$, with $\dot{\varphi} = 1/r_0$, and the limit $\beta \to 1, \beta^2 \to 4, r_0^2 \to 0, \varphi = 1$, yields the identity map $z = \zeta$.

We recall that circles $q$-constant in the $\xi$-plane represent a family of confocal ellipses in the $z$-plane, with major and minor principal semi-axes equal to $r_0 |\dot{\varphi} \pm 1/\dot{\varphi}|/2$, respectively, whereas lines $\varphi$-constant represent the biorthogonal family of confocal hyperbolae. For this system, it is easy to show that

$$z_w = r_0 \cos (\varphi - i\chi_w), \quad \dot{z}_w = r_0 \exp(-i\chi_w) \cos (\varphi - i\chi_w), \quad \chi_w = -\ln \varphi_0$$

(48)

$$h_w = r_0 |\sin (\varphi - i\chi_w)|, \quad n_2 = e^{i(\varphi - \varphi_0)} = i \frac{r_0}{h_w} \exp (\varphi - i\chi_w)$$

(49)

Furthermore, (40) and (41) reduce to

$$f = \frac{r_0^2 h_0^3}{8 \varphi_0^3} \left( 1 - \varrho_0^2 \right) \cos \varphi + i(1 + \varrho_0^2) \sin \varphi \right] d\varphi \quad (50)$$

$$\tau = -\frac{r_0^2 h_0^3}{8 \varphi_0^3} \left( 1 - \varrho_0^2 \right) \varphi_0 \sin \varphi \right] d\varphi \quad (51)$$

Considering first the case of pure translation, $x_2 = e^{\text{inh}}$, $\omega = 0$ in (34), one readily finds by means of (48), (49) that the right-hand side of (38) is given by

$$h_w U_+ = \partial_\varphi \Psi_+ = h_w \Re \left\{ z_2 e^{i(\varphi_0 - \varphi)} \right\} = \frac{r_0}{2\varphi_0} \left[ \cos (\varphi - \varphi_0) - \varrho_0^2 \cos (\varphi + \varphi_0) \right]$$

(52)

Here, $\partial_\varphi$ represents the angle of translation relative to the major principal axis of the ellipse B. Hence, $n = 1, \theta = \Theta_M(\varphi)$, and (53) and (42) then give the nondimensional force and torque as

$$f = -\frac{r_0^2 h_0^3}{2(1 + k_1) \varphi_0^3} \left[ (1 - \varrho_0^2) \cos \varphi_0 + i(1 + \varrho_0^2) \sin \varphi_0 \right]$$

(54)

$$\tau = \frac{2}{1 + \beta^2} \left[ \beta^2 \cos \varphi_0 + \beta^{-2} \sin \varphi_0 \right], \quad \tau = 0$$

(55)

where $r_0$ denotes the magnitude of the force for $\beta = 1$ on a circular cylinder. The quantity $\beta^2 = (b/a)^2$ represents the ratio of drag for translation parallel and perpendicular to the major principal axis, respectively. One factor $b/a$ represents the effect of body cross-section on melt inflow, and the remaining factor $(b/a)^2$ represents lubrication force.

The strong dependence on $(b/a)^2$ in (54) on cross-sectional form clearly differs from the formulae of Ref. 7 Eqs. 1A–1C for the case $\epsilon=0$, which appear to ignore the effect of body shape on local film thickness and, hence, on the distribution of lubrication pressures and melting temperatures on $\partial B$.

The effect of body shape is suggested by the previous work of Ref. 23 for slightly elliptic cylinders, with $\beta = 0 \leq \epsilon < 1$, although they consider the modification of drag only in the direction of the minor principal axis. It is easy to see from (54) that the drag relative to the circular cylinder should be modified by factors $(1 \mp 2\epsilon)$, respectively, in the directions of the major and minor principal axes, whereas Tyvand and Beijang (Eq. 42) obtain a factor $(1 + 3\epsilon/2)$ for the latter.

For the case of pure rotation, $x_2 = 0$ in (34), it follows from (48) to (49) that

$$h_w U_+ = -h_w \Re \left\{ n_2 u_2 \right\} = -\frac{r_0^2}{2} \sin 2\varphi$$

(55)

Again, (42)–(44) give an harmonic form, distinct from (53), with $n = 2$ and

$$\Theta_M(\varphi) = \frac{\varrho_0^2}{4(1 + k_1)} \sin 2\varphi, \quad \Theta = \Theta_M(\varphi) \varphi^{\pm 2},$$

(56)

for $\varphi \gtrless 1$, with $r_0^3 = (1 + k_1)/2$.

Hence, after some algebra, one finds by means of (51) and (56) that

$$\tau = -\frac{r_0^2 h_0^3}{4(1 + k_1)} \omega$$

(57)

We recall that $r_0$ and $\varrho_0$ in (54) and (57) are given by (47) in terms of the axis ratio $\beta$. By choosing the
characteristic velocity in (13) as $U=ax$, we may take $\omega \equiv 1$ in (55)–(57). Given the definition of $r_0$, we note the strong dependence of torque in (57) on eccentricity of the elliptic cylinder. Also, we note the doubly periodic form of (55) implies two melting and two regelation zones generated by local rotational pressure or tension.

When translation and rotation are combined, $h_W \ U_{a_n}$ is given by the linear combinations of the harmonics in (52) and (55). As one may readily verify, (42)–(44) are no longer compatible with the implied harmonic forms for \( \Theta \) and \( \Theta_M \). As indicated by the following analysis, the class of harmonic solutions are even more restricted in three dimensions.

**Axisymmetric bodies in three dimensions**

As it is doubtful that arbitrary body shapes admit solutions involving a single harmonic, we specialize immediately to axisymmetric bodies, laying out the general theory and then considering the special case of spheroids. For later reference, we recall that Nye’s exact solution to (14)–(16) for spheres with arbitrary $\epsilon$ yields a constant film thickness $t$ given by (28) with $k_1$ replaced by $2k_1$, and a nondimensional force given in the present notation as

$$f = \frac{8h_1^3}{3r^3} \; \text{with } r^3 \to (1+2k_1) \; \text{for } \epsilon \to 0 \quad (58)$$

For more general axisymmetric bodies, we adopt the conformal map (28) considered above, and, as a variant on the notation of Hobson, pp. 410 ff., we let $X, Y, Z$ denote Cartesian coordinates, where $Z$ represents the axis of symmetry of body $B$, and

$$X+iY=Re^{i\Phi}, \quad R^2=X^2+Y^2, \quad z=Z+iR=Re^{i0}, \quad r^2=|z|^2=R^2+Z^2 \quad (59)$$

where $x_i=R, Z, \Phi$ and $x_i=r, \theta, \Phi$ represent cylindrical and spherical polar coordinates with unit basis vectors $e_i$, respectively. Then, as an extension of (31), we can represent real 3-D space vectors $u$ as elements $u$ of an abstract two-dimensional (2-D) complex vector space defined by the invertible linear transformation

$$u = u_x e_x + u_y e_y + u_\Phi e_\Phi \rightarrow u = u(\mathbf{u}) = \begin{bmatrix} u_x \\ u_y \\ u_\Phi \end{bmatrix}$$

where

$$u_x = u_z + u_r, \quad u_r = |u_x| \cos (\Phi-\Phi_0), \quad u_\Phi = -|u_x| \sin (\Phi-\Phi_0) \quad \begin{bmatrix} |u_x| \end{bmatrix} = \left(u_x^2 + u_y^2\right)^{1/2} \quad \Phi_0 = \arctan (u_y/u_x), \quad u = u_x e_x + u_y e_y$$

with

$$u_x^2 = u_z v_z + u_r v_r = u \cdot v + i (u \times v) \cdot e_\Phi, \quad \text{where } u = |u_z, u_r|$$

defining a scalar product given by the standard rules for matrix multiplication.

By means of the circle map $z(\zeta)$, an axisymmetric surface, $R = R_W(2\zeta)$ or $r=r_W(\theta)$, can be mapped into the sphere $0 < \Phi < 2\pi, 0 < \theta < \pi, \Theta \equiv 1$. Then, with metrical coefficients for the orthogonal systems $\Phi, \zeta, \eta$

$$h_{\Phi} = R(\zeta, \eta) = |\zeta(\zeta)|, \quad h_{\zeta} = h_\eta = |\zeta'| = 1/|\zeta'|$$

the Laplacian becomes

$$\nabla^2 = \mathbb{R} \left\{ \frac{1}{R} \partial_R \partial_R + \frac{1}{R^2} \partial_\Phi \partial_\Phi \right\} = \frac{1}{h_{\zeta}^2 R} \left\{ \partial_\zeta (R \partial_\zeta) + \partial_\eta (R \partial_\eta) \right\} + \frac{1}{R^2} \partial_\Phi^2$$

\[
\equiv \frac{1}{h_{\zeta}^2 R} \left\{ \partial_\zeta (R \partial_\zeta) + \frac{1}{a^2} \partial_\Phi (R \partial_\Phi) \right\} + \frac{1}{R^2} \partial_\Phi^2 \quad (62)
\]

and (16) reduces to

$$\frac{1}{R_W} \left[ \partial_\Phi \left( \frac{R_W h_W^3}{R_W} \partial_\Phi \Theta_M \right) + \partial_{\Theta_M} \left( \frac{R_W h_W^3}{h_W} \partial_{\Theta_M} \Theta_M \right) \right] = -h_W U_{\alpha} = -\partial_\Phi \Psi +$$

where $R_W(\phi) = R_{|\phi|=1} \equiv h_\phi |\phi=1$ and $h_W(\phi) = h_\phi |\phi=1$ as in (39), and the element of area on $W$ is $dA = R_W h_W d\phi d\Phi$. Hence, as a variant of (40) and (41), and in a form complementary to (60), the force and torque are now given by (40) and (41)

$$\left[ \begin{array}{c} f_x \\ f_y \\ f_z \end{array} \right] = \frac{2N_1^3}{\pi} \int_0^\pi \int_0^{2\pi} \Theta_M \left[ \begin{array}{c} e^{\Phi} \sin (\phi - \sigma_W) \\ e^{\Phi} \cos (\phi - \sigma_W) \end{array} \right] R_W h_W d\phi d\Phi,$$

with $f_\perp = f_x + i f_y \quad (64)$

$$\tau_{xz} = \tau_{xy} = \frac{2N_1^3 \pi}{\int_0^\pi \int_0^{2\pi} \Theta_M e^{\Phi} \sin (\phi - \sigma_W) R_W h_W d\phi d\Phi,}$$

As indicated in a different notation by Hobson, p. 411, Laplace’s equation based on the first form in (62) admits separable solutions of the form

$$\Theta = F_x F_y \exp (\pm i m \Phi), \quad \text{for } R(\zeta, \eta) = \exp (G),$$

$$G = G_\zeta + G_\eta, \quad h_\zeta^2/R^2 = H_\zeta + H_\eta \quad (66)$$

where the subscripts, doing double duty, serve to designate distinct functions as well as their arguments. Then, with primes denoting derivatives with respect to these arguments, the functions $F$ must satisfy the ordinary differential equations

$$F'_z + H_\zeta F_z + (\lambda_\zeta - m^2 H_\zeta) F_z = 0$$

with

$$x = \zeta, \eta, \lambda_\zeta = -\lambda_\eta = \text{const.} \quad (68)$$

**Restricted shapes**

With similar notation, another class of separable solutions

$$\Theta = F_x F_y \exp (\pm i m \Phi)$$

arises for special cross-sectional shapes

$$h_\zeta^2/R^2 = H_\zeta + H_\eta \quad (69)$$

The functions $F_z$ again satisfy (67) with, in lieu of (68)

$$x = \zeta, \eta, \lambda_\zeta = -\lambda_\eta = \text{const.} \quad (70)$$

and are more relevant to the example considered below.

Since the surface normal $n$ for axisymmetric bodies has $n_\Phi = 0, n_\zeta = n_\eta$, independent of $\Phi$, it follows from (34) to (35) that for the pure translation $z_\zeta = \cos \phi_0 + i \sin \phi_0 \cos (\Phi-\Phi_0)$, $\alpha \equiv 0$, the surface-normal velocity is

$$U_{\alpha} = \mathbf{z} \cdot \mathbf{n} \mathbb{R} \left\{ z_\zeta n_\zeta \right\} = \cos \phi_0 \cos (\phi - \phi_0) - \sin \phi_0 \sin (\phi - \phi_0) \cos (\Phi-\Phi_0) \quad (71)$$
Hence, (14)–(16) admit single harmonics in Φ only for \( \vartheta_0=0, \pi/2 \), which corresponds, respectively, to translation parallel or perpendicular to the symmetry axis, with \( m=0,1 \) in (67) and (70), respectively.

Conversely, for pure rotation, \( \varpi=0 \), it is easy to show that
\[
U_\varpi = n \cdot (\omega \times \mathbf{x}_W) = -3 (n_z \omega_z) \Theta_0 \tag{72}
\]
where the notation for components is that used in (60). Although the dependence on \( \Phi \) that is similar to that of (71), the different dependence on \( \varphi \) generally rules out a simple harmonic solution for simultaneous rotation and translation, as is the case for the planar problem considered above and as will be made clear below.

Letting
\[
G_\varphi = R_W^2 / h_W, \quad \Theta_0 = \Phi \cos m(\Phi - \Phi_0),
\]
with \( \Theta = \Phi \Theta_M, \quad \Psi = S(q) \Theta_M, \quad \text{and} \quad F_\varphi = 1 \) at \( q=1 \),
\[
\Theta_0 = \frac{h_W U_n}{M} \tag{73}
\]
where \( \Theta_0 \) is a constant, we can reduce (42) and (63) to the form
\[
F_\varphi + G_\varphi F_\varphi + \left[ \frac{h_W M}{r^3} - m^2 \frac{h_W}{R_W^2} \right] F_\varphi = 0, \quad \text{where} \quad \Theta_0 = \frac{h_W U_n}{M} \tag{74}
\]
and \( M \) is defined by (44) with \( F_\varphi \equiv F_\varphi \). Compatibility with (67) requires that \( t(\varphi) \) satisfy
\[
\tau^2 = \frac{M h_W}{\lambda_\varphi + m^2 (h_W / R_W^2 - h_\varphi)} \tag{75}
\]
where \( \lambda_\varphi \) is an appropriate characteristic value, and subscripts \( \perp \) again refer to values at \( q=1 \).

To clarify these results, we consider the case of spheroids and the associated spheroidal harmonics.\(^{27}\)

The cases of prolate and oblate spheroidal coordinates\(^{27}\) Ch. X** are covered, respectively, by the substitutions
\[
\{ \hat{x}, \hat{y} \} \rightarrow \left\{ \begin{array}{ll} \hat{Z}, \hat{R} & \mbox{(prolate)} \\ \{ \hat{R}, \hat{Z} \} & \mbox{(oblate)} \end{array} \right. \tag{76}
\]
in (45)–(47), with \( h_W = r_0 |\sin (\varphi - \vartheta_0)| \), \( \vartheta_0 = -\ln q_0 \), according to (48) and (49). As the two geometries are related by a simple alteration of the map (45), we focus attention first on prolate spheroids and summarize key results for the oblate spheroids below.

**Prolate spheroids**

Then, the appropriate special case of (69) and (70) is
\[
\lambda_\varphi = n(n+1), \quad n=1,2, \ldots, \quad G_\varphi = \ln \varphi,
\]
\[
H_\varphi = \frac{1}{\sin^2 \varphi}, \quad G_\varphi = \frac{4}{(\varphi^2-1)^2}, \quad H_\varphi = \frac{4q_0}{(1-q_0^2)^2} \tag{77}
\]
\[
R_W(\varphi) = \frac{r_0}{2q_0} (1-q_0^2) \sin \varphi, \quad H_W = \frac{4q_0}{(1-q_0^2)^2}
\]
and (75) takes on the form (43), with
\[
\tau_3 = \frac{F_\varphi}{n(n+1) + m^2 H_W} \tag{78}
\]

The solutions \( F_\varphi, F_\varphi \) to (67) are both associated Legendre functions,\(^{27}\) the latter given by multiples of the regular surface harmonics \( P_n^m(\cos \varphi) \) and the former by \( P_n^m(\varphi) \) or \( Q_n^m(\varphi) \), inside and outside the surface \( W \), respectively, with \( \lambda = \ln q \), where \( \lambda = \ln q \) is the variable appearing in (45)–(47).

The relations (71) and (72) now take on the simpler forms, for translation
\[
h_W U_n = \frac{1}{2q_0} \left[ (1-\varphi_0^2) \varphi \cos \vartheta_0 \cos \varphi \right.
\]
\[
+ (1+\varphi_0^2) |\varphi_0| \sin \vartheta_0 \sin \varphi \cos (\Phi - \Phi_0) \right] \tag{79}
\]
and, for rotation
\[
h_W U_n = \frac{|\varphi_0| \sin 2 \varphi \sin (\Phi - \Phi_0)}{2} \tag{80}
\]
with \( \Theta_0 \) given by the second equation of (74). Owing to axial symmetry, we may without loss of generality set \( \Phi_2 = 0 \) and \( \Phi_0 = 0 \) equal to zero.

In view of the well-known expressions for associated Legendre functions and their derivatives,\(^{27-29}\) it is evident that (81) involves two distinct surface harmonics, with \( n=1 \), \( m=0 \), and \( P_1^0 = P_1 = \cos \varphi \), and with \( n=1, m=1 \), \( P_1^1 = \sin \varphi \), respectively, whereas (82) involves a single harmonic with \( n=2, m=1 \), and \( P_1^1 = -3 \sin 2 \varphi / 2 \). We note that the doubly periodic form for \( n=2 \) involves two melting and two regulation zones, as was the case with rotation of elliptic cylinders. Then, for each pair of integers \( n, m \) we have a distinct harmonic motion, with
\[
F_\varphi = \begin{cases} P_n^m (\cosh \chi) / P_n^m (\cosh \vartheta_0), & \varrho \leq 1, \\ Q_n^m (\cosh \chi) / Q_n^m (\cosh \vartheta_0), & \varrho \geq 1, \end{cases}
\]
where \( \vartheta_0 \) is given by (78) and the Legendre functions are given for real arguments \( \varphi \) by

---

Figure 2. Force and torque on prolate spheroids as functions of axis ratio $\beta$, given by Table 2 and (89), with forces in (a) and (b) normalized by force on sphere ($\beta=1$), and with torques in (c) normalized by torque on elliptic cylinder having same $\beta$.

From these results and (79), (80), it is a simple matter to derive the nondimensional forces and torques shown as space vectors in Table 2, where subscripts $\parallel$, $\perp$ refer to vector projections parallel and perpendicular to the symmetry axis, respectively, and where, with proper scaling, $\mathbf{a}$ and $\mathbf{e}$ represent unit vectors.

The factors $M$ are given as functions of $\beta$ by well-known formulae for the Legendre functions. Also, we recall once again that the parameters $r_0, \varrho_0$ are given in terms of the axis ratio $\beta$ by (47).

**Oblate spheroids**

Summarized here are the major changes of the above results for prolate spheroids. In particular, replacing $\tilde{z}(\zeta)$ in (45) by $z = i\tilde{z}(\zeta)$ requires the following modifications. First, (77) is replaced by

\begin{align*}
G_\varphi &= \ln \cos \varphi, & H_\varphi &= \frac{1}{\cos^2 \varphi}, & G_\zeta &= \ln \left( \tilde{z}^2 + 1 \right), \\
H_\varphi &= \frac{4}{\left( \tilde{z}^2 + 1 \right)^2}, & R_\varphi(\varphi) &= \frac{r_0}{2\varrho_0} \left( 1 + \varrho_0^2 \right) \sin \varphi, & H_\varphi &= \frac{4\varrho_0^2}{\left( 1 + \varrho_0^2 \right)^2}
\end{align*}

whereas (79), (80) become

\begin{equation}
M = \frac{s}{c^2 - 1} \left\{ (n+1)(k_1-1)c + (n-m+1) \left[ \frac{P^m_{n+1}(c)}{P^m_n(c)} - \frac{Q^m_{n+1}(c)}{Q^m_n(c)} \right] \right\},
\end{equation}

for $n=1, 2, m=0, 1$, with $c = \cosh \mathcal{X} = \frac{1 + \varrho_0^2}{2\varrho_0}, \quad s = \sinh \mathcal{X} = \frac{1 - \varrho_0^2}{2\varrho_0}$
As the harmonics associated with (86) are $P_n^m(\cos \varphi)$ and $P_n^m(\sinh \psi)$, the relations (83)–(85) carry through, with $\chi$ and $\chi_N$ replaced everywhere by $\chi^+ e^\frac{\psi}{2}$, respectively.

It is easy to verify that the forces given in Table 2 and (89) reduce to (58) when the spheroid becomes spherical. Otherwise, these results involve a shape dependence made evident by Figure 2, which presents calculations of various coefficients in Figure 2a exhibits singular behavior at $\kappa_1=0$, reflecting a physical singularity for bodies B with infinite conductivity. This is clearly a 3-D effect, as no such singularity arises in the 2-D case. Once again, the shape dependence is not captured by Nye's formula\textsuperscript{7} Eq. 15 for Case (1 A), $\epsilon=0, \kappa_1=0$.

Conclusions

The foregoing generalization of the work of Nye provides analytic results for drag force and torque on solid elliptic cylinders and spheroids moving through ice under the action of pressure melting, regulation, and flow in a lubricating water layer. The analysis is based on the assumption of negligible thermal resistance of the water layer which allows for special harmonic solutions for various uncoupled translations and rotations of elliptic cylinders and spheroids. The results show a dependence on body shape not captured by the certain formulae proposed by Nye, and they indicate a concomitant variation of the water-layer thickness $t$ as the 1/3-power of the surface-normal metrical coefficient. There is an interesting question as to whether this variation of $t$ may remain valid for more complicated motions, a question that might possibly be settled by numerical solution of the general equations proposed earlier.

The present analysis suggests simple experiments involving slow steady rotation of solid bodies such as elliptic cylinders in a stationary block of ice, as an alternative to unsteady experiments involving translation of a wire or other solid body. Such experiments could provide easier experimental observation and serve to elucidate certain discrepancies between the Nye theory and experiment, perhaps leading to improvements in the theory such as those proposed by Drake and Shreve.\textsuperscript{12}

Although the present analysis is devoted to analytical solutions for the case of thermally thin melt layers around simple body shapes, it by no means excludes experiments on more complex geometries. In that regard, it is worth recalling that, despite its ubiquity and unique molecular properties, water is by no means the only candidate for the kind of experiment considered above. As indicated by the Clapeyron equation, the pressure-melting will generally occur in any substance with negative volume of fusion, a subject of considerable and sustained theoretical interest in its own right.\textsuperscript{30–34} Although the extreme conditions of melting, or the optical opacity of solid and liquid, would rule out experiments of the type appropriate to the water–ice system, there remain certain interesting possibilities. A cursory review of the literature turns up a wide variety of materials exhibiting contraction on melting, including lanthanide and actinide metals\textsuperscript{35}; germanium\textsuperscript{36,37}; gallium and bismuth\textsuperscript{38,39}; alkali halides\textsuperscript{40}; some alkali nitrates;\textsuperscript{41} certain macromolecular compounds\textsuperscript{42} and, possibly, diamond.\textsuperscript{43}

Acknowledgments

Many years ago an undergraduate at the University of Illinois UIUC listened, awe-struck, to an elegant seminar on the thermodynamics of fluid flow presented by a rising academic star from the University of Wisconsin and alumnus of the U of I. The erstwhile undergraduate offers this article as modest tribute to the star who has continued to shine so brightly over the intervening years.
