I. INTRODUCTION

Inclusive charged-particle distributions have been measured in proton-proton (pp) collisions at the LHC for different center-of-mass energies [1–7]. These measurements provide insight into the strong interaction (QCD) at low energy scales and show that predictions of current phenomenological models cannot fully describe the measured observables in all kinematic regions. As shown in Ref. [2], the limitation of models is particularly apparent when particles with low transverse momentum \( p_T < 500 \text{ MeV} \) are studied. Specifically, discrepancies are observed in the description of

(i) the charged-particle density as a function of pseudorapidity, \( dN_{ch}/d\eta \);
(ii) the shape of the charged-particle multiplicity distribution both at low and high multiplicities;
(iii) the shape of the charged-particle multiplicity distribution for both \( p_T < 500 \text{ MeV} \) and \( p_T > 3 \text{ GeV} \); and
(iv) correlations between the average \( p_T \) of charged particles per event, \( \langle p_T \rangle \), and the charged-particle multiplicity \( n_{ch} \).

Some of these discrepancies may be reduced through the development of parametrizations for the models of nonperturbative QCD and their adjustments (tunes) that better match model predictions to the latest measurements with particles produced at very low \( p_T \). Nevertheless, it is also possible that a new formulation of certain components of these phenomenological models is needed.

Many of the difficulties in accurately describing observables dominated by low-\( p_T \) QCD phenomena stem from the fact that there is often a combination of nonperturbative effects, including soft diffraction, low-\( p_T \) parton scattering and hadronization. These effects act simultaneously in a given kinematic region and are difficult to separate experimentally. The recent ATLAS study of inclusive charged-particle production [2] shows that the sensitivity of measurements to some of these effects depends on the definition of the kinematic region in which the measurements are made. Typically, the more inclusively the sample is defined, or the more soft particle activity is added to the measurement, the larger the disagreement is between the data and the models.

Hadronization, the mechanism of hadron formation from quark and gluon cascades, must be taken into account in all measurements involving hadrons. The flows of energy, momentum and flavor of hadrons approximately follow those of partons [8]. The mechanism of hadron formation, however, can only be described with the aid of phenomenological models. The two main models employed in multipurpose event generators are the string (Lund) fragmentation model [9] and the cluster model [10].

A proposed modification of the Lund string model [11] evokes the possibility of the formation of a helixlike structured gluon field at the end of the parton cascade. Such a structure corresponds to the optimal packing of soft gluons in the phase space under helicity conservation requirements. Most notably, the helix string model imposes correlations between the adjacent break-up points along a string with observable effects in the inclusive \( p_T \) distribution and in the azimuthal ordering of direct hadrons, i.e. hadrons produced directly from the string fragmentation.

In this paper, the correlations in the charged-hadron azimuthal angle \( \phi \) [12] are studied for two different schemes of hadron ordering using data recorded with the ATLAS detector. The results are corrected for detector effects and compared with the predictions of various Monte Carlo (MC) event generators. The paper is organized as follows: the observables are described in Sec. II. Section III describes the ATLAS detector, and Sec. IV presents the MC samples used in the study. The track and event selection are detailed in
Sec. V. The analysis and the uncorrected data distributions measured at the center-of-mass energy of $\sqrt{s} = 7$ TeV are presented in Sec. VI. The procedure to correct for detector and selection effects and an overview of systematic uncertainties can be found in Sec. VII (additional information is provided in Appendix B). The last section of the paper is devoted to a comparison of corrected data with models and a discussion of the results. Appendix A presents results with $\sqrt{s} = 900$ GeV.

**II. OBSERVABLE QUANTITY**

The presence of azimuthal ordering, stemming from the underlying QCD string structure, is studied for two different variants of the helix-like ordered gluon field. As suggested in [11], the azimuthal ordering of hadrons should be observable with the help of a power spectrum defined according to the expected structure of the helix field. Assuming the break-up of the string occurs via tunneling [9], with the partons emerging at rest, the azimuthal direction of the hadron's intrinsic transverse momentum coincides with the phase of the helix string in the center of the string piece, which forms the hadron. Hence, the azimuthal opening angle of two direct hadrons measures the phase difference between two corresponding points along the string, with the transverse plane defined with respect to the string axis. The analysis takes advantage of the fact that in soft $pp$ interactions, the QCD strings tend to be aligned along the beam axis.

In close analogy with [11], where the authors assume the helix winding is proportional to the rapidity difference between hadrons, we define the power spectrum

$$S_\eta(\xi) = \frac{1}{N_{\text{ev}}} \sum \frac{1}{n_{\text{ch}}} \left| \sum \Delta \eta \exp(i(\xi \eta - \phi_j)) \right|^2,$$  \hspace{1cm} (1)

where $\xi$ is a parameter and $\eta_j$ ($\phi_j$) is the pseudorapidity (azimuthal angle) of the $j$-th hadron, $N_{\text{ev}}$ is the number of events, and $n_{\text{ch}}$ is the number of charged hadrons in the event. The inner sum runs over charged hadrons in the event and the outer sum over events in the sample.

It is important to note that the form of the helix field is not well constrained and that it is possible to find several parameterizations of the helix field conforming to the assumptions made in [11]. One possible scenario [13] corresponds to a static, regular helix structure with the phase difference $\Delta \phi$ proportional to the amount of internal energy stored in the fraction $f$ of string with mass $M_0$:

$$\Delta \phi = SfM_0 = S\kappa \Delta l = S\Delta E,$$  \hspace{1cm} (2)

where $S$ is a parameter, $\kappa$ is the string energy density, $\Delta \phi$ is the difference in the helix phase between two points along the string and $\Delta l$ and $\Delta E$ are the length and the energy, respectively, of the corresponding string piece in its rest frame. The energy-distance $\Delta E$ along the string between direct hadrons is not directly observable but according to MC studies, the signature of the helix-shaped field should be visible with help of a very loose approximation of the string by a chain of hadrons ordered in pseudorapidity. For the purpose of measuring the azimuthal ordering, we thus retain two parameters for each final hadron: the azimuthal angle $\phi$ and the position $X$ along the chain, evaluated as

$$X_j = 0.5E_j + \sum_{k<j} E_k,$$  \hspace{1cm} (3)

where $E_k$ is the energy of the $k$-th hadron in the chain, and the position of the hadron is associated with the center of the corresponding string piece. Accordingly, we define an alternative power spectrum

$$S_E(\omega) = \frac{1}{N_{\text{ev}}} \sum \frac{1}{n_{\text{ch}}} \sum \exp(i(\omega X_j - \phi_j)) \left| \frac{\sum \exp(i(\omega X_j - \phi_j))}{\sum \exp(i(\omega X_j - \phi_j))} \right|^2,$$  \hspace{1cm} (4)

where $\omega$ is a parameter. The inner sum runs over pseudorapidity-ordered charged hadrons in the event.

The presence of a helix-like angular ordering of hadrons of either type would manifest itself as a peak in the corresponding power spectrum; the position of the peak would indicate the density of the helix winding. It should be stressed that, though formally very similar, $S_\eta$ and $S_E$ are only loosely correlated. A modified form of the helix string implies a difference in the experimental signature, such that the presence of a helix gluon field creating a peak in $S_E$ does not necessarily result in a peak structure in $S_\eta$ and vice-versa.

The power spectra can also be expressed as a sum of contributions from pairs of hadrons

$$S_\eta(\xi) = 1 + \frac{1}{N_{\text{ev}}} \sum \frac{1}{n_{\text{ch}}} \sum \cos(\xi \eta_j - \phi_{ij}),$$  \hspace{1cm} (5)

$$S_E(\omega) = 1 + \frac{1}{N_{\text{ev}}} \sum \frac{1}{n_{\text{ch}}} \sum \cos(\omega X_{ij} - \phi_{ij}),$$

where $\Delta \phi_{ij} = \phi_j - \phi_i$ is the opening azimuthal angle between hadrons, $\Delta \eta_{ij} = \eta_i - \eta_j$ is their pseudorapidity difference and $\Delta X_{ij} = X_j - X_i$ their energy-distance as defined above. The absence of correlations corresponds to $S_\eta(\xi) = 1$ and $S_E(\omega) = 1$.

**III. ATLAS DETECTOR**

The ATLAS detector [14] covers almost the entire solid angle around the collision point with layers of tracking detectors, calorimeters and muon chambers. It has been designed to study a wide range of physics topics at LHC energies. For the measurements presented in this paper, the trigger system and the tracking devices are of particular importance.

The ATLAS inner detector has full coverage in $\phi$ and covers the pseudorapidity range $|\eta| < 2.5$. It consists of a
silicon pixel detector, a silicon strip detector (SCT) and a transition radiation tracker (TRT). These detectors are immersed in a 2 T axial magnetic field. The pixel, SCT and TRT detectors have typical \( r - \phi \) position resolutions of 10, 17 and 130 \( \mu \)m, respectively, and the pixel and SCT detectors have \( r - z \) position resolutions of 115 and 580 \( \mu \)m, respectively. A track traversing the full radial extent would typically have 3 silicon pixel hits, 8 and more silicon strip hits and more than 30 TRT hits.

The ATLAS detector has a three-level trigger system: level 1 (L1), level 2 (L2) and the event filter (EF). For this measurement, the L1 trigger relies on the beam pickup timing devices (BPTX) and the minimum bias trigger scintillators (MBTS). The BPTX are composed of electrostatic beam pickups attached to the beam pipe at a distance \( z = \pm 175 \) m from the center of the ATLAS detector. The MBTS are mounted at each end of the detector in front of the liquid-argon endcap-calorimeter cryostats at \( z = \pm 3.56 \) m and are segmented into eight sectors in azimuth and two rings in pseudorapidity (2.09 < |\( \eta \)| < 2.82 and 2.82 < |\( \eta \)| < 3.84). Data were taken for this analysis using the single-arm MBTS trigger, formed from BPTX and MBTS L1 trigger signals. The MBTS trigger was configured to require one hit above threshold from either side of the detector. The MBTS trigger efficiency was studied with a separate prescaled L1 BPTX trigger, filtered to obtain inelastic interactions by inner detector requirements at L2 and EF [2].

IV. MONTE CARLO SAMPLES

The analysis has been developed using a PYTHIA 6.421 [15] (MC09 tune [16]) sample with large statistics, fully simulated [17] and reconstructed using the standard ATLAS reconstruction chain [18]. It should be stressed that the choice of the MC tune does not affect the outcome of the analysis because the data are corrected in a model-independent way.

For the comparison of the corrected data with the standard hadronization models, MC samples produced with PHOJET 1.12.1.35 [19], HERWIG + + 2.5.1 [20] (LHC-UE7-2/MU900-2 tunes [21]), PYTHIA 8.130 (4C tune [22]) and a recent tune of PYTHIA 6 (AMB2b [23]) have been used. The MC generators PYTHIA and PHOJET employ the Lund string fragmentation model whereas the HERWIG MC is based on the cluster model. To study the sensitivity of the power spectra to the modification of the string fragmentation model, the data are also compared with an alternative implementation of the fragmentation process based on the helix string field described by Eq. (2) [24].

V. DATA SAMPLES

The measurements reported in this paper were made using \( pp \) collision data recorded at \( \sqrt{s} = 7 \) TeV. The data were collected with stable colliding beams at 7 TeV and correspond to an integrated luminosity of \( \sim 190 \mu b^{-1} \) from the beginning of the 2010 LHC run [2]. A sample of \( pp \) collision events recorded at \( \sqrt{s} = 900 \) GeV corresponding to an integrated luminosity of \( \sim 7 \mu b^{-1} \) [2] was also studied and the results are shown in Appendix A.

A. Event and track selection

Events are selected using the following criteria:

(i) the event has at least one trigger hit in MBTS;

(ii) the event has one and only one reconstructed vertex and this vertex must have at least three associated tracks;

(iii) the event has no tracks with \( p_T > 10 \) GeV;

(iv) the event has at least six reconstructed tracks (\( n_t > 5 \)) passing the requirements below.

The requirements on reconstructed tracks included in the analysis are the following:

(i) the track is reconstructed by the track reconstruction algorithm used in [1], with an implicit cut on the transverse momentum, \( p_T > 100 \) MeV, and more than 6 hits in the silicon detectors;

(ii) the track has a transverse impact parameter with respect to the primary vertex \( |d_0^{PV}| < 2 \) mm;

(iii) the track has a longitudinal impact parameter with respect to the primary vertex \( |z_0^{PV}| \sin(\theta) < 2 \) mm; and

(iv) the track is reconstructed in the pseudorapidity range \(-2.5 < \eta < 2.5\).

The requirement on the minimum number of tracks ensures full trigger efficiency [2]. The contributions from the beam and noncollision background (cosmic rays and detector noise) have been investigated in [2] and found to be negligible. Events with multiple primary vertices (less than 0.3% of the sample and subsamples defined below) are rejected in order to prevent a bias from multiple \( pp \) interactions in the colliding proton bunches.

B. Subsample definitions

The analysis is carried out in parallel on the sample selected as described above (henceforth referred to as the “inclusive sample”) and on two subsamples.

The first subsample contains events where the transverse momentum of any reconstructed track does not exceed 1 GeV (\( \max(p_T) < 1 \) GeV). This subsample is called the “low-\( p_T \) enhanced sample.” The effects of parton showering and lateral boost are diminished in this selection. The \( \max(p_T) < 1 \) GeV requirement selects events with little acollinear jet activity and thus the transverse activity is expected to be primarily sensitive to hadronization effects.

The analysis is also performed on a second subsample defined by a higher track \( p_T \) cutoff, \( p_T > 500 \) MeV. This particular selection yields a subsample with a significantly reduced contribution from diffractive \( pp \) interactions
TABLE I. Average charged-particle multiplicity $N_{\text{ch}}^{\text{gen}}$ and relative fraction of diffractive events for the fully simulated PYTHIA6 (MC09) MC sample at $\sqrt{s} = 7$ TeV. Results are shown for events selected with the corrected charged-track multiplicity cutoff $n_{\text{ch}} > 10$ (detector level) and $n_{\text{ch}}^{\text{gen}} > 10$ (particle level) (* indicates before the max($p_T$) cut correction).

(see Table I). This subsample is referred to as the “low-$p_T$ depleted sample”.

C. Selection criteria at particle level

The comparison between corrected data and MC models requires an adjustment of the event selection in order to avoid a systematic bias. The analysis relies on two main selection criteria: the charged-hadron $p_T$ and the charged-hadron multiplicity.

The effect of the low $p_T$ cutoff is easily modeled at the particle level (MC truth [25]) and the corresponding systematic uncertainty is covered by the uncertainty assigned to the correction procedure, described in Sec. VII. The cut on the maximal $p_T$ of a track is more selective when applied at the particle level as it removes also those MC events which contain a nonreconstructed high $p_T$ track. The effect is non-negligible in the low-$p_T$ enhanced sample, where it is corrected for and a systematic uncertainty is assigned to reflect the additional uncertainty.

The charged-track multiplicity selection criteria on the measured data need to be modified in order to emulate MC modelling. The adjustment of the charged-track multiplicity is done in the following way: for each reconstructed track, a random number RND is repeatedly generated according to a flat distribution until RND $< \varepsilon_{tr}$, $\varepsilon_{tr}$ being the estimated track reconstruction efficiency [26]. The corrected charged-track multiplicity $n_{\text{ch}}$ corresponds to the number of random numbers generated for the entire event. The procedure also contains an additional correction for the residual content of secondary tracks.

The selection based on $n_{\text{ch}}$ roughly reproduces the average charged-particle multiplicity of the particle-level sample selected with a $n_{\text{ch}}^{\text{gen}}$ cutoff (see Table I). Figure 1 illustrates the effect of hadron-level cuts on the true charged-particle multiplicity $n_{\text{ch}}^{\text{gen}}$. The choice of the selection cut for the current analysis ($n_{\text{ch}} = n_{\text{ch}}^{\text{gen}} > 10$) is aimed at minimizing any bias in the power spectra related to the loss of events due to the detector-level charged-track multiplicity cutoff $n_{tr} > 5$.

The selection criteria distinguishing between data samples are summarized in Table II, which also provides the information about the final number of events retained for the analysis and the mean corrected charged-track multiplicity of each sample. The relative fraction of diffractive events (based on the nominal cross-section) and the mean charged-particle multiplicity of the Monte-Carlo selection are given in Table I.

The final track selection contains $2.8 \pm 0.4\%$ of secondary tracks according to studies performed on simulated samples. Nonprimary tracks predominantly arise from hadronic interactions with detector material, photon conversion to electron-positron pairs and decays of long-lived particles. The average reconstruction efficiency for primary charged particles is $75\%$ for the $p_T > 100$ MeV track selection and $84\%$ for the $p_T > 500$ MeV selection. The systematic uncertainty due to the performance of the track reconstruction is estimated following the studies performed in Ref. [2].

VI. ANALYSIS METHOD

For the measurement of $S_E$, the selected tracks are ordered by pseudorapidity and a pion mass is assigned to each of them. According to MC estimates, the charged-particle sample contains about 86% pions, 9.5% kaons, 4% protons/antiprotons and a negligible number of leptons ($\sim 0.5\%$). The effect of assuming a pion mass would need to be taken into account for a precision measurement of the position of the signal but its impact on the comparison of data with MC models is negligible. For the calculation of $S_\eta$, no mass assumption is required. The power spectra are measured as $(S_E - 1)$ and $(S_\eta - 1)$ for convenience.

The uncorrected power spectra are shown in Fig. 2 as a function of the azimuthal opening angle (helix phase difference) per unit of energy distance ($S_E$) and per unit of pseudorapidity ($S_\eta$) for the three samples. All angles are expressed in radians throughout the paper.

MC studies show that the power spectra are sensitive to various kinds of correlations between particles. The dominant peaks seen in both distributions arise due to the jet structure and momentum conservation in the hard parton-parton scattering. The position of these peaks depends on the visible energy (in the case of $S_E$) and the pseudorapidity range (in the case of $S_\eta$) used in the analysis. Their height is sensitive to a number of physics processes, notably the amount and structure of multiple parton interactions, cross-talk between overlapping hadronic systems (color reconnection), and parton shower properties. Note, that the values of $S_E(\omega = 0)$ and $S_\eta(\xi = 0)$ are identical by definition. They are closely related to the average opening angle between particles in the transverse plane. The presence of azimuthal correlations stemming from the properties of the gluon field should be visible as an additional positive peak or enhancement in the power spectrum and the modification should be more pronounced in the low-$p_T$ region, where the fragmentation and parton interactions have comparable effects on the transverse momentum of hadrons.

The comparison of the uncorrected data obtained in the inclusive event selection and in the low-$p_T$ enhanced/depleted subsamples shows the size of the peaks diminishing with the decreasing track $p_T$ selection range, a feature we may associate with the relative fraction of high $p_T$ jets in the sample.

VII. CORRECTION PROCEDURE AND SYSTEMATIC UNCERTAINTIES

The data are corrected for nonreconstructed charged particles with the help of an unfolding technique based on [27] and described in Appendix B.

The correction for the secondary track content is obtained using a random sampling of secondary tracks according to the parametrized secondary track rate obtained from fully simulated MC. The contribution from tracks labeled as secondary ($\delta S^{\text{sec}}$) is subtracted from the measured data distribution. Typically, it amounts to $\sim 6\%$ of the size of the peak in the power spectrum.

An additional correction is applied in the low-$p_T$ enhanced sample to compensate for the bias introduced by the selection cut on max($p_T$) in case the track with highest $p_T$ was not reconstructed. Selecting events with exactly one track above the threshold, the power spectra ($S^{p_T}$) are calculated using all the other tracks in the event. The correction is obtained by subtracting $S^{p_T}$ from the data in the proportion corresponding to the probability for the high-$p_T$ track being lost in the reconstruction.

All corrections are model independent. The correction procedure has been verified by checking the procedure on fully simulated MC samples.

**A. Systematic uncertainties**

The principal sources and parametrizations of systematic uncertainty associated with the corrected data are summarized in Table III. The combined systematic uncertainty has the following components:

(i) residual bias of the folding procedure (Appendix B): obtained from the comparison of distributions reconstructed at the detector level using samples with full detector simulation and those obtained with the folding technique;
(ii) uncertainty of the unfolding technique: parametrized to cover the residual discrepancies in the scaling of 3 folding iterations (Appendix B);
(iii) uncertainty on the tracking efficiency estimate: dominated by the uncertainty on the inner detector material description, which translates into a variation of scaling factors by 5%;
(iv) uncertainty due to the residual content of secondary tracks: set to 25% of the correction applied, with minimal value of 0.005 (based on MC studies);
(v) uncertainty due to the difference in the charged-particle multiplicity selection at the generator level and at the detector level: calculated in a model-independent way as a variation of the shape corresponding to the change of the averaged selected charged-particle multiplicity by one unit; and
(vi) the uncertainty in the correction of the bias due the $\max(p_T)$ cut: corresponds to a 5% variation of the track reconstruction efficiency.

All contributions to the systematic uncertainty are combined quadratically. The negative correlation between track reconstruction efficiency and secondary track content is neglected, making the uncertainty estimate more conservative.

**VIII. RESULTS**

The results of this analysis obtained for $pp$ collisions at $\sqrt{s} = 7$ TeV are presented in this section. Results from
this analysis repeated for $\sqrt{s} = 900$ GeV are shown in Appendix A. The corrected data are compared with the predictions of several commonly used MC models: PYTHIA6, PHOJET, PYTHIA8 and HERWIG++.

Figure 3 shows the comparison for the inclusive event selection ($n_{\text{ch}} > 10$, $p_T > 100$ MeV and maximal $p_T < 10$ GeV). The principal peak structure observed in the power spectra for both $S_E$ and $S_\eta$ is roughly reproduced by PYTHIA and PHOJET models and overestimated by HERWIG++. The tail of the $S_E$ distribution around $0.5 < \omega < 1$ rad/GeV is not reproduced by any of the models.

Hadronization effects should become more evident when measurements are made in regions of the phase space dominated by the production of low-$p_T$ particles. Figure 4 shows the power spectra measured in the low-$p_T$ enhanced sample ($n_{\text{ch}} > 10$, $p_T > 100$ MeV and maximal $p_T < 1$ GeV). A significant amount of correlations in observed in the data in both $S_E$ and $S_\eta$ distributions compared to the PHOJET and PYTHIA based models. HERWIG++ gives a seemingly better description for the $S_E$ distribution yet it seems its prediction is more of an artifact of an enhanced single jet structure given the fact the model overestimates the measurements in the inclusive event selection (Fig. 3). The interpretation of this measurement in terms of the azimuthal ordering of hadrons related to the properties of the gluon field is discussed in Sec. VIII A.

Figure 5 shows the power spectra $S_E$ and $S_\eta$ for the corrected data and MC predictions in the low-$p_T$ depleted region ($n_{\text{ch}} > 10$, $p_T > 500$ MeV and maximal $p_T < 10$ GeV). In principle, this should be the best understood part of the phase space, with a suppressed diffractive component, lower sensitivity to hadronization effects and best available model tunes. However, we find that all models significantly overestimate the size of the principal peak structure in both $S_E$ and $S_\eta$.

Comparison of Figs. 3–5 show that the azimuthal correlations are qualitatively different in each subsample, and that the standard MC models fail to reproduce these accurately. Similar conclusion can be drawn for the measurement performed at $\sqrt{s} = 900$ GeV (Appendix A).

In the frame of the conventional QCD modelling, we have tried to identify the most likely source of the observed...
discrepancies. Figure 6 shows the sensitivity of the $S_\eta$ distribution to various components of the QCD modeling implemented in PYTHIA 6, taking as a baseline the nondiffractive $pp$ scattering scenario (indicated by the full line). In the low-$p_T$ depleted sample, the size of correlations varies strongly with the amount of multiple parton interactions (MPI), of initial state radiation (ISR) and with the amount of parton showering. The data prefer modelling with enhanced radiation and/or enhanced MPI rate which can be achieved via careful adjustment of the relevant model parameters. However, such an adjustment typically creates an even larger discrepancy in the low-$p_T$ enhanced region, where the parton shower and ISR have smaller influence. Inversely, the removal of the MPI and of the diffractive processes increases the size of the peak in the modeling of the low-$p_T$ enhanced region, but none of these rather extreme variations lead to a good agreement with the measured $S_\eta$ distribution, while creating a huge discrepancy in the low-$p_T$ enhanced region. We conclude that for both measured spectra, the conventional models fail to describe the low-$p_T$ enhanced region, where the data are consistently showing a larger and broader peak structure.

A. Alternative fragmentation model

The question of compatibility of the measurements with the azimuthal ordering signal originating from the underlying structure of the QCD field is studied using the PYTHIA6-based helix string model implementation [24] of the modified helix string scenario corresponding to the $S_E$ definition (Eq. (2)). The comparison of corrected data with the PHOJET modelling of $pp$ interactions, interfaced alternatively with the standard string fragmentation and with the helix string fragmentation, is shown in Figs. 7 and 8. It is seen that the helixlike gluon ordering improves the description of the data in the inclusive sample for $S_E$ as it generates higher values in the region of $\omega \in (0.5, 1)$. In the low-$p_T$ enhanced sample the data are more strongly peaked than the model. This indicates the data have a more jetlike structure than predicted by PHOJET which means the model may need readjustment beyond the fragmentation part.

It is possible that the original helix string proposal [11] provides an improved description of the $S_\eta$ measurement but we cannot verify this hypothesis due to the absence of
the MC implementation of this variant of the helix string model for parton configurations containing hard gluons.

In principle, the position of the azimuthal ordering signal allows a measurement of the characteristic density of the helix string winding (parameter $S$ in Eq. (2)). The data indicate $S$ in the range $0.5$ to $0.9$ rad/GeV. However, the interplay between string fragmentation and the other processes (such as parton showering, color reconnection and multiple interactions) is not sufficiently understood to allow a more precise estimate (the measurement has to rely on MC description for the correction of the longitudinal boost).

IX. CONCLUSIONS

A measurement of the ordering of charged hadrons in the azimuthal angle with the ATLAS data recorded from proton-proton collisions at $\sqrt{s} = 7$ TeV and $\sqrt{s} = 900$ GeV has been presented.

A spectral analysis of correlations between the opening azimuthal angle and the longitudinal separation of the charged hadrons was performed by measuring the $S_E$ and $S_\eta$ power spectra. These measurements were done in three kinematic regions (inclusive, low-$p_T$ enhanced and low-$p_T$ depleted samples) that were specifically defined to help assess the potential contribution of hadronization effects to the power spectra by varying the levels of competition between hadronization and other QCD effects.

The results were compared with the expectations of various MC event generators. Predictions generated by the MC models employing the standard Lund string fragmentation model roughly reproduce the data in the inclusive sample.

The models systematically overestimate the size of correlations in the low-$p_T$ depleted sample, where the observables are sensitive to the multiple jet structure of events (due to the presence of underlying event and/or parton showering).

For observables measured in the low-$p_T$ enhanced sample, none of the models investigated describes the data adequately. A study showing the impact of extreme variations in MC model parameters that are known to contribute to soft-QCD effects demonstrates that, although some improvement of predictions for $S_E$ and $S_\eta$ can be achieved in the low-$p_T$ enhanced sample, it is still far from satisfactory.

The measurement of $S_E$ in the kinematic region dominated by low-$p_T$ particles shows features similar to those seen in models in which the fragmenting QCD strings are represented by helixlike ordered gluon chains. These measurements suggest that the inclusion of such azimuthally-ordered fragmentation effects could be one factor in improving current models of soft particle production and hadronization.

ACKNOWLEDGMENTS

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; ARTEMIS, European Union; INFN-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINEVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERSYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular, from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

TABLE V. Average charged-particle multiplicity $N_{ch}^{gen}$ and relative fraction of diffractive events for the fully simulated PYTHIA6 (MC09) MC sample at $\sqrt{s} = 900$ GeV. Results are shown for events selected with the corrected charged-track multiplicity cutoff $n_{ch} > 10$ (detector level) and $n_{ch}^{gen} > 10$ (particle level) (*) indicates before the max($p_T$) cut correction.
average corrected charged-track multiplicity are shown in Table IV. For comparison, the average charged-particle multiplicity of PYTHIA6 MC09 samples is shown in Table V, together with the fraction of diffractive events in the sample (the estimate is based on the nominal cross section obtained from the generator). The corrected data are compared to the particle-level prediction of various models in Fig. 9.

APPENDIX B

The deconvolution technique employed in this analysis is a model-independent procedure suitable for observables with linear dependence on the track reconstruction efficiency. The dependence of the shape of the measured distribution on the fraction of reconstructed tracks is studied by convolution with the track reconstruction
efficiency matrix ("double-folding"): the reconstructed tracks are randomly rejected from the sample according to the parametrized reconstruction efficiency and the power spectra are recalculated. The procedure is repeated two more times, so that a sequence of three folding iterations is available for each measured distribution. The folding iterations, together with the measured distribution and the deconvoluted (MC truth) distribution, obey simple scaling rules:

(i) the size of correlations (along the $S-1$ axis) scales linearly with the multiplicity (physically it depends on the fraction of correlated pairs which have quadratic multiplicity dependence, partially compensated by the normalization factor in Eqs. (1) and (4)).

(ii) the shape of the power spectrum $S_{E}$ scales linearly in $\omega$ with the fraction of energy removed from the hadron chain (in $S_{\eta}$, the position of the peak stays nearly constant).

A typical example of the variation of the power spectrum with the number of applied folding iterations is shown in Fig. 10 on a PYTHIA6 sample with inclusive event selection. Secondary tracks are removed from the samples in Figs. 10 and 11.

FIG. 10 (color online). Power spectrum calculated at the generator level, detector level and following three folding iterations as described in the text. Secondary tracks are removed from the samples in Figs. 10 and 11.

The deconvolution of the power spectrum requires finding a set of scaling factors $f_y, f_x(x = \omega, \xi)$ which fulfill the requirement

$$s_{i-1}(x) - 1 = \frac{1}{f_y} \left[ s_i \left( \frac{x}{f_x} \right) - 1 \right],$$

$$0 < x < 10, \quad 0 < i < 4,$$  \hspace{1cm} (B1)

where $s_i$ designates the $i$-th folding iteration of the power spectrum ($i = 0$ for uncorrected data, $-1$ for corrected data).

The knowledge of a single pair of consecutive iterations is sufficient to calculate the scaling factors. Typically, they are determined using the difference between uncorrected data and the first folding iteration (1 $\rightarrow$ 0). The stability of the scaling factors is verified by applying them on the folding iterations of higher orders ($2 \rightarrow 1, 3 \rightarrow 2$) while the residual discrepancies serve as a basis for the estimate of the associated systematic uncertainty (Fig. 11). The deconvoluted power spectrum is obtained with the help of Eq. (B1) as the extrapolated (0 $\rightarrow$ −1) member of the sequence of folding iterations.

FIG. 11 (color online). The closure test of the scaling deconvolution method. Follow-up of the scaling precision over several folding iterations allows to verify the stability and to estimate the associated systematic error.

The origin of observed correlations may be diverse, with variable dependence on the track reconstruction efficiency. A better precision can therefore be obtained by splitting the observed distribution empirically into components and by estimating the scaling factors per component.

The power spectra calculated in this paper can, to good approximation, be fit with a combination of a Landau distribution [28] (to describe the resonant peak structure), an exponentially falling background (driven by local momentum conservation of adjacent hadron pairs) and a polynomial of first or second degree to describe the upper tail of the distribution. In practice, the subtraction of a single background term and determination of 2–3 effective scaling factors is sufficient to describe the difference between a pair of folding iterations; the replacement of the $f_x$ with an attenuated scaling factor $f_x \rightarrow f_x' = (f_x + x)/(1 + x)$ helps smooth the transition into the upper part of the spectrum.

The knowledge of a single pair of consecutive iterations is sufficient to calculate the scaling factors. Typically, they are determined using the difference between uncorrected data and the first folding iteration (1 $\rightarrow$ 0). The stability of the scaling factors is verified by applying them on the folding iterations of higher orders ($2 \rightarrow 1, 3 \rightarrow 2$) while the residual discrepancies serve as a basis for the estimate of the associated systematic uncertainty (Fig. 11). The deconvoluted power spectrum is obtained with the help of Eq. (B1) as the extrapolated (0 $\rightarrow$ −1) member of the sequence of folding iterations.
