Supporting Information

ABSTRACT: Multiferroic materials have simultaneous magnetic and ferroelectric long-range orders and can be potentially useful for a wide range of applications. Conventional ferroelectricity in oxide perovskites favors nonmagnetic electronic configurations of transition metal ions, thus limiting the number of intrinsic multiferroic materials. On the other hand, this is not necessarily true for multiferroic fluorides. Using molecular beam epitaxy, we demonstrate for the first time that the multiferroic orthorhombic fluoride $\text{BaCoF}_4$ can be synthesized in thin film form. Ferroelectric hysteresis measurements and piezoresponse force microscopy show that the films are indeed ferroelectric. From structural information, magnetic measurements, and first-principles calculations, a modified magnetic ground state is identified which can be represented as a combination of bulk collinear antiferromagnetism with two additional canting spin orders oriented along orthogonal axes of the $\text{BaCoF}_4$ unit cell. The calculations indicate that an anisotropic epitaxial strain is responsible for this unusual magnetic ground state.

KEYWORDS: multiferroics, thin films, fluorides, ferroelectricity, antiferromagnetism

1. INTRODUCTION

Multiferroic materials exhibit exciting physical phenomena related to the simultaneous presence of multiple long-range orders, in many cases consisting of antiferromagnetism and ferroelectricity. To date, the majority of studies on multiferroic materials have been devoted to oxide perovskites in the form $\text{ABO}_3$. The conventional ion transfer ferroelectricity mechanism in oxide perovskites is known to rely on the covalent bonds between oxygen and B-site cations with closed-shell, nonmagnetic electronic configurations. Therefore, the search for magnetic ferroelectrics should be directed toward alternative ferroelectricity mechanisms. Alternatives can be found in the fluoride family which contains many examples of magnetic ferroelectrics. The best known example is the $\text{BaMF}_4$ compound, where $\text{M} = \text{Mn}, \text{Fe}, \text{Co}, \text{or Ni}$. Recent theoretical studies focused on their magnetoelcetric and multiferroic properties. To the best of our knowledge, however, only studies of bulk form $\text{BaMF}_4$ have been reported in the scientific literature. Because thin films are essential for potential electronic device implementations, including heterostructure integration with existing architectures, it is important to determine whether these materials can be synthesized in thin film form, and whether the multiferroicity can be retained if growth strain is applied.

$\text{BaMF}_4$ compounds crystallize in orthorhombic lattice with the space group $\text{Cmc}2_1$. Distorted $\text{MF}_6$ octahedra share corners in the ac-plane, forming puckered sheets which are separated by $\text{Ba}$ ions along the b-axis (Figure 1a). Their long-range ferroelectric (FE) order theoretically originates from $\text{MF}_6$ octahedra rotations about the a- and polar displacements of $\text{Ba}$ cations along the c-axis. The combination of these two effects results in geometric proper ferroelectricity. The FE switching barrier is expected to be of the same order of magnitude for the whole family of $\text{M} = \text{Mn}, \text{Co}, \text{Fe}, \text{Ni}$. Previous experiments in bulk single crystals demonstrated FE switching with c-axis saturation polarizations of $P_s = 8.0 \mu \text{C/cm}^2$ and $6.7 \mu \text{C/cm}^2$ and FE Curie temperatures of 1153 and 1593 K in $\text{BaCoF}_4$ and $\text{BaNiF}_4$, respectively, but no switching in $\text{BaFeF}_4$ and $\text{BaMnF}_4$. The lack of FE switching in $\text{BaFeF}_4$ was explained by the increased conductivity of crystalline samples. However, the theoretical analysis of Ederer and Spaldin has suggested that FE switching in the Mn and Fe compounds may require electric fields larger than those applied in the experiments. Note that a similar crystal structure and geometrical (or topological) ferroelectricity have recently been studied in the orthorhombic oxide polyemorph $\text{LaTaO}_4$, and therefore our results can be relevant to this broader class of materials.

2. EXPERIMENTAL AND COMPUTATIONAL METHODS

2.1. Thin Film Growth. Single-side polished Al₂O₃ (0001) substrates (MTI Corp. USA) were cleaned and then annealed in a tube furnace at 1200 °C for 2 h in air in order to clean and reconstruct the surface. Once loaded into the MBE growth chamber, all substrates were annealed in vacuum at 700 °C for 1 h before reducing the temperature to the desired growth temperature. Films of BaCoF₄ were deposited by codeposition of BaF₂ and the appropriate transition metal fluoride, CoF₂, using commercial Knudsen cells. Prior to the growth, the deposition rates of each material were measured by a quartz crystal monitor placed at the position of the substrate holder, and then the rates were adjusted to achieve the proper stoichiometry. Typical growth rates for BaF₂ were 0.005 nm/s, while the growth rates for CoF₂ were adjusted accordingly to achieve a 1:1 molar ratio between both constituents. Typical growth rates were 0.006–0.007 nm/s for BaCoF₄. Several sets of substrate temperatures, Tₛ = 300–500 °C, were tested in order to optimize the structural quality of the samples. The best growth, as judged from the X-ray diffraction measurements, was achieved at Tₛ = 350–400 °C. The total thickness of BaCoF₄ films was adjusted to 100 nm.

Pt interdigitated electrodes were deposited on Al₂O₃ substrates prior to the growth of BaCoF₄ thin film samples later used for FE measurements. Pt was deposited by DC magnetron sputtering at room temperature at growth rates of 0.033 nm/s to the total film thickness of 50 nm. Standard ultraviolet optical photolithography procedures were used to create the photosist mask for interdigitated electrodes. The electrodes consisted of 25 pairs of fingers separated by a 2.5 μm gap, with a finger length of 0.5 mm and a width of 5 μm.

2.2. Structural Characterization. Structural characterization of the thin films was performed by X-ray diffraction using a Rigaku Cu rotating anode source, a Huber four-circle goniometer, and a bent
crystal graphite monochromator tuned to the Cu Kα radiation (0.15418 nm wavelength).

2.3. Magnetic Measurements. Magnetization measurements were performed using a Magnetic Properties Measurement System (MPMS) based on a Superconducting Quantum Interference Device (SQUID) sensor from Quantum Design. All measurements were corrected by subtracting the magnetic response from a blank, diamagnetic Al2O3 substrate.

2.4. Ferroelectric Hysteresis Loops. In-plane FE polarization of the thin films was measured using PT interdigitated electrodes deposited on top of the substrate and covered by the film during its growth. FE hysteresis measurements were performed using a Precision LC tester from Radiant Technologies. Each hysteresis loop was averaged 250 times. Thin film samples were mounted in a closed-cycle helium cryostat from CryoMech and cooled to a base temperature of approximately 14 K. Electrical contacts between tester wires and the interdigitated electrodes were made with indium.

In order to remove the effects of the relatively large parallel capacitance associated with the wires running through the cryostat, as well as of current leakage effects, the remanent hysteresis option was used as implemented into the Radiant tester software. This approach is essentially an extension of the PUND (Positive Up Negative Down) method but applied to the hysteresis measurements. A preset unipolar triangular voltage pulse was applied prior to each bipolar triangular voltage pulse used for the actual polarization measurement. Depending on the field direction of the preset pulse with respect to the field direction during the first half of the subsequent measurement pulse, the corresponding loop is then labeled as unswitched or switched. Switched and unswitched loops were performed for both positive and negative initial field directions. The difference between switched and unswitched loops was used to extract the contribution to the overall field direction during the corresponding loop is then labeled as unswitched or switched.

2.5. Piezoresponse Force Microscopy. PFM measurements were performed at room temperature using the Asylum Research MFP-3D AFM system. Platinum-coated silicon cantilevers (Olympus OMC-1-AC240TM) were used in the measurements. PFM amplitude and phase were measured at the contact resonance frequencies of the probes, typically around 360 kHz.

2.6. First-Principles Calculations. First-principles calculations were performed within Density Functional Theory (DFT) as implemented in the Vienna Ab initio Simulation Package (VASP). Projector augmented wave (PAW) pseudopotentials were used to represent the valence and core electrons. The electronic configurations taken into account in pseudopotential as valence electrons were Ba (5s5p63d1), Co (3s3d34s2), and F (2s2p2). The exchange correlation was represented within the General Gradient Approximation (GGA) and Perdew–Burke–Ernzerhof for Solids (PBEsol) parametrization. Due to the magnetic character of these systems, the spin polarization was considered in the calculation with the proper use of an exchange correlation functional (LSDA). The periodic solution of these crystalline structures was represented by Bloch states with a Monkhorst–Pack with a 4×4×6 k-point mesh and a 600 eV energy cutoff, which has been previously demonstrated to give converged forces to less than 0.0001 eV/Å. Additionally, the correct description of the d-electron localization was achieved through the DFT+U approximation with U = 4.0 eV. Spin–orbit coupling (SOC) in the noncollinear analysis was included according to the implementation by Hobbs et al. In order to take into account the AF magnetic interactions along the a-axis, a 2×1×1 (48 atoms) cell was used for all the calculations. Finally, the spontaneous polarization was computed within the Berry phase approach as implemented in VASP.

3. RESULTS AND DISCUSSION

3.1. Material Parameters and Substrate Considerations. The choice of substrates suitable on which to grow BaMF3 films is nontrivial because the orthorhombic unit cell makes it difficult to find a substrate with a good in-plane lattice match. For reference, the lattice parameters for M = Co are a = 4.21 Å, b = 14.63 Å, and c = 5.85 Å. In our experiments, Al2O3 (0001) single crystalline substrates (hexagonal unit cell a = 4.763 Å, c = 12.991 Å) were used. As shown in Figure 1b, four (010) unit cells of BaCoF4 can fit along the [001] direction, consisting of five (0001) unit cells of Al2O3 along [1120], which results in theoretical lattice mismatches along the a-axis of 2.0% (compressive strain) and −1.8% (tensile strain) along the c-axis.

3.2. Growth and Structural Characterization. Thin films were grown under ultrahigh vacuum conditions using molecular beam epitaxy (MBE). Two constituents, BaF2 and CoF2, were coevaporated in 1:1 molar rates. The out-of-plane X-ray diffraction (XRD) scan on the best quality 100 nm BaCoF4 film (Figure 2a) shows a predominant (010) orientation, with the secondary orientation peaks (170), (190) and (1110) adjacent to (008), (0100), and (0120) peaks, respectively. That is, formation of stalking faults in the ab-plane causes a deviation from the preferential (010) orientation. In the projection onto the ab-plane, the unit cell contains four BaCoF4 monolayers (Figure 1a). The (150) orientation was not observed, possibly because the angle between (150) and (0006) planes is 35°, which is much larger than the angles of 26°, 21°, and 18° for the observed reflections from the (170), (190), and (1110) planes, respectively. No additional impurity phases were observed. Additional tests provided no evidence for the formation of BaxCoFy and Ba3CoF10 impurity phases (see the Supporting Information). Rocking curves measured at the (040) BaCoF4 Bragg condition (Figure 2b) showed full-widths at half-maximum (FWHM) of 0.58°. The corresponding rocking curve of the (0006) peak of Al2O3 substrates was FWHM = 0.25° (Figure 2b), which was limited by the instrumental resolution. Φ-scans around the BaCoF4 (040) and Al2O3 (1014) peaks are shown in Figure 2c. The symmetry of the peaks can be explained in both materials by the formation of three in-plane structural twin
domains rotated by 120° with respect to each other. The polar c-axis in each of the twin domains grew along the Al₂O₃ substrate’s three ⟨110⟩ directions, as shown in Figure 1b.

Based on the asymmetrical scans of the BaCoF₄ (041), (082), (111), (222), and (333) peaks, the unit cell parameters were calculated to be \(a = 4.20 \pm 0.01 \text{ Å}, b = 14.56 \pm 0.01 \text{ Å},\) and \(c = 5.93 \pm 0.01 \text{ Å}\). These values are in agreement with the compressive and tensile strains imposed by the Al₂O₃ substrates, since the in-plane \(a\)-lattice parameter was reduced by 0.2% and the \(c\) lattice parameter increased by 1.4% with respect to the bulk values. The reduction of the \(a\) lattice constant was within the experimental error, however, and therefore cannot be completely proven. The in-plane lattice mismatch also led to a decrease of 0.5% for the out-of-plane lattice parameter \(b\), also with respect to the bulk. In summary, the films were strained by the interaction with the substrate, mostly along the polar c-axis, with the parameter \(b\) adopting a new value. The unit cell volume of BaCoF₄ increased by 0.6 ± 0.3% with respect to the bulk.

3.3. Ferroelectric Properties. 3.3.1. Ferroelectric Hysteresis Loops. BaMF₄ compounds are expected to have FE polarizations along the crystallographic c-axis. In our case, this means that the electric field should be applied in the film plane. This was achieved by depositing interdigitated electrodes directly on the substrate surface prior to the film growth (see the Supporting Information and Figure 3a). A separate sample without the electrodes was grown simultaneously in order to verify the film crystal quality by X-ray diffraction.

Figure 3. Ferroelectric hysteresis measurements. a: Interdigitated electrodes were deposited on the Al₂O₃ substrate and covered with the film. The electric field direction was aligned perpendicular to one of the structural twin domains (polar c-axis noted as red arrow) and at 30° with respect to the other two (blue and gray). Electrodes are separated by 2.5 μm. b: Remanent ferroelectric polarization vs applied electric in-plane field measured on a BaCoF₄ thin film at \(T = 14 \pm 2\text{ K}\).

The electrodes were aligned such that the electric field direction applied during the measurements was perpendicular to the polar c-axis of one twin domain and at 30° with respect to the other two domains (Figure 3a). Therefore, assuming the three in-plane crystal orientations are equally weighted, the measured response should be \(1/\sqrt{3}\), or approximately 58% of the single twin domain polarization. The leakage of the samples at room temperature was relatively high, and thus reliable FE hysteresis loops could not be measured. To minimize the leakage, FE measurements were performed at a temperature \(T \approx 14\text{ K}\).

Remanent hysteresis loops were measured up to a maximum electric field of 3.95 \(\times 10^6\) V/m, as shown in Figure 3b. The remanent polarization of the largest loop was \(\approx 1.1\ \mu\text{C/cm}^2\), which is of the same order of magnitude as the 8.0 \(\mu\text{C/cm}^2\) measured in the bulk. Actual hysteresis loops have never been published for bulk BaCoF₄, to the best of our knowledge. We therefore tentatively compare our loops with data reported for BaZnF₄. Typical coercive fields for BaZnF₄ were reported to depend strongly on the ac field frequency, ranging from 1.0 \(\times 10^6\) to 6.0 \(\times 10^8\) V/m for ac field frequencies between 0.01 and 100 Hz, respectively. Since our measurements were performed with 100 ms electric field pulse duration, corresponding to a 10 Hz field frequency, and therefore a 3.35 \(\times 10^8\) V/m coercive field would be expected if the compound were BaZnF₄. In our case, the measured coercive fields were \(\approx 2.5 \times 10^7\) V/m. In order to compare the two results, the semiempirical scaling law for the coercive field \(E_c\) vs distance between contacts \(d\), \(E_c(d) \approx d^{-2/3}\), can be used. Using the separation between contacts of 2.5 μm, a calculation reveals that BaZnF₄ should have \(E_c = 1.41 \times 10^8\) V/m or approximately six times larger than the value measured in our BaCoF₄ film. It is unclear whether this difference is due to an intrinsic property of the Co compound or if \(E_c\) was reduced by the presence of defects in the film.

Regarding the maximum remanent polarization measured in BaCoF₄ we note that, taking into account the presence of the three in-plane domains, the actual polarization should be 3 times the measured polarization or \(\approx 2\ \mu\text{C/cm}^2\). This is still lower than the value of 8.1 \(\mu\text{C/cm}^2\) measured in the bulk material, but there are other factors that may have led to an underestimate; for example, there could be regions in the film that had larger switching fields than we were able to apply with our technique.

3.3.2. Piezoresponse Force Microscopy (PFM). PFM was performed at room temperature to characterize the microscopic polar domains and FE properties of the BaCoF₄ films. Typical topography image and PFM responses are shown in Figure 4a. A root-mean-squared (rms) surface roughness of 3.0 nm was observed across the sample, while the PFM responses revealed a granular sub 100 nm domain pattern. PFM data were acquired using the out-of-plane flexural vibrational mode of the cantilever. The in-plane torsional mode was also monitored but did not yield a significant signal, possibly due to thecantilever’s high torsional rigidity. In the experiments, a small ac drive voltage of 1 V at the cantilever contact resonance frequency was applied to the buried electrodes array, while the scanning probe was kept at the ground potential. Underneath the probe tip, a localized electric field \(E_{tip}\) was generated with both an out-of-plane field component and opposite in-plane components at opposing sides of the tip (Figure 4b). The surface deformation of the film with in-plane polar c-axes in response to \(E_{tip}\) is illustrated in Figures 4c and 4d. In the middle of a domain, the out-of-plane deformation was small and mainly coupled to the cantilever’s flexural mode through a weak shearing force (Figure 4c). However, at the boundary between two domains with head-to-head polarizations, the in-plane gradient of \(E_{tip}\) induced a large out-of-plane deformation which strongly coupled to the cantilever’s flexural vibration mode (Figure 4d). In the special case when the c-axis was perpendicular to the cantilever, the torsional shearing response was not detectable by flexural PFM.

The phase of the PFM signal induced by shearing force depended on the relative orientation between the local c-axis and the probe cantilever. In contrast, the PFM signal induced by out-of-plane deformations at domain boundaries was independent of such orientation changes. Therefore, information on the local c-axis orientations could be extracted by comparing the PFM phases after sample rotations (Figure 4e). Note that as expected, the overlayed PFM amplitude image in Figure 4e showed the strongest signals at domain boundaries.
PFM results also supported the presence of three different c-axis orientations deduced from XRD measurements. Figure 4f shows the histograms of the phase differences $\Delta \phi$ measured after rotating the sample by 180° in two orthogonal configurations. The values of $\Delta \phi$ were concentrated mostly around 0 and $\pm \pi$. Values around $\Delta \phi = 0$ corresponded to domain boundaries and domains with polar c-axes perpendicular to the cantilever, while values around $\Delta \phi = \pm \pi$ corresponded to domains with nonzero polarization components along the cantilever orientations. As expected, in the configurations when the cantilever was perpendicular to one of the c-axis orientations indicated by XRD (colored red in Figure 4f), the distribution at $\Delta \phi = 0$ increased significantly.

To evaluate the FE properties of the nanodomain structures, an in-plane electric field was applied by biasing the interdigital electrodes. Restricted by leakage, dc electric fields ($E$) between $-3.1 \times 10^7$ V/m and $4.2 \times 10^7$ V/m were applied. Figure 5 shows the PFM images taken in a 175 nm × 175 nm area after the application of different in-plane electric fields for 30 s. Areas enclosed by yellow dashed curves indicate regions switched by electric field.
did not switch contained twin domains with their polar axes largely perpendicular to \( E \) and other regions that required higher electric field to switch.

Head-to-head domain boundaries were identified from regions with large PFM amplitudes and opposite phases at opposing sides, as discussed above. PFM amplitudes at such locations were tracked as a function of \( E \). In principle, because large electric fields aligned the polarizations of adjacent domains, the PFM amplitude was expected to be minimized at both field polarities as illustrated in Figure 5b. However, when one domain required a switching field larger than what was possible in the experiments, the PFM amplitude evolution was expected to be different (Figure 5c). In the experiment two separate spots were studied. One spot (left, Figure 5d) was located between the electrodes, while the other one, as a control experiment, was located on top of a buried electrode (right, Figure 5d) where the in-plane field was zero. Large hysteretic changes of PFM amplitude were only observed in the first case and resembled the situation of a limited domain switching, as illustrated in Figure 5c. The fact that some domains required a much larger switching field than others might originate from a preferred polarization direction in the film or other reasons related to leakage.

### 3.4. Magnetic Properties.

Zero-field cooling (ZFC), field cooling (FC), and thermoremanent magnetizations (TRM) were measured as a function of temperature by heating in a magnetic field applied after cooling in zero-field, during cooling in nonzero field, and upon heating in zero-field after a FC procedure, respectively. Figure 6a shows magnetization \( M \) vs \( T \) data with \( H \) applied in the plane of the sample for a BaCoF\(_4\) thin film. A broad maximum was observed at approximately 80 K, which is relatively close to the expected maxima which occur at 90–110 K in the bulk. There was no splitting between the ZFC and FC curves at the 80 K maximum down to approximately 50 K (inset in Figure 6a), indicating that this transition corresponds to collinear AF bulk-like spin order. The low temperature magnetic response showed two additional transitions at \( T_{C1} = 19 \) K and \( T_{C2} = 41 \) K, which are not observed in bulk BaCoF\(_4\). Both transitions seem to correspond to weak ferromagnetic (WFM) order because of the relatively low magnetization values and the shape of the hysteresis loops, as discussed above. Qualitatively, the new magnetic transitions can be explained by the strain in the films. The largest strain was along the \( c \)-axis, which is also the direction of the AF vector \( L_c \) for collinear order \( L_c = s_1 - s_2 \). Spin moments at different \( Co \) sites labeled in Figure 1c. Therefore, a more pronounced modulation of the bulk spin order by the strain is expected. The two transitions were also visible in the TRM (Figure 6b). Surprisingly, the remanent magnetization could be prepared by cooling in magnetic fields aligned both in the film’s plane and out of the film’s plane. These results are consistent with the first-principles calculations, discussed in more detail below, which show that two additional magnetic spin cantings, along the \( b \)- (out of the film plane) and \( a \)- (in the film plane) axes, are energetically favorable when strain is taken into account. In particular, the additional canted AF order as allowed in BaCoF\(_4\) along the \( b \)-axis is then again similar to analogous AF canted order \( L_c \) along the \( c \)-axis theoretically predicted for BaNiF\(_4\).

Additional information about the magnetic transitions in BaCoF\(_4\) was provided by in-plane magnetic hysteresis loops measurements shown in Figure 6c. Hysteresis loops measured at \( T = 5 \) K had a shape similar to other WFM materials, such as YFeO\(_{3.43}\). The remanent magnetization was approximately 0.05 \( \mu_B \) per formula unit, which agrees well with typical values for weak ferromagnetism and is in agreement with the theoretical value of 0.03 \( \mu_B \) per formula unit derived from our \textit{ab initio} calculations discussed below. Magnetic fields up to 30 kOe were necessary to saturate the loop at \( T = 5 \) K. This feature is also typical for WFM thin film materials and can be explained by the existence of domains with the spin canting magnetization parallel (low saturation fields) and perpendicular (high saturation fields) to the applied magnetic field direction. These domains are due to the structural domains rotated by 120° with respect to each other present in our samples. Magnetic hysteresis loops measured at temperatures \( T > 20 \) K showed mostly a linear response with closed loops. An s-shaped response at low fields, that was persistent up to room temperature, was also observed and can be explained by superparamagnetic impurities in \( Al_2O_3 \) substrates, as verified by measurements on blank substrates.

### 3.5. First-Principles Calculations.

Spontaneous polarization and noncollinear magnetism in BaCoF\(_4\) thin films were calculated using density functional theory assuming epitaxial strain and structural lattice parameters similar to the experimental values obtained from thin films grown on \( Al_2O_3 \) (0001) substrates. The thermal stability of the strained BaCoF\(_4\) phase was tested via phonon dispersion calculations using the lattice parameters obtained from XRD scans (+1.2% along the \( a \)-axis and +0.5% along the \( c \)-axis with respect to the theoretically optimized bulk cell parameters, \( a_0 = 4.1556 \) Å, \( b_0 = 14.4981 \) Å, and \( c_0 = 5.9034 \) Å). No imaginary frequencies...
(unstable modes) were found, indicating that the bulk space group $\text{Cmc2}_1$ for this strain value was stable without additional structural transitions.

In order to determine the impact of the strain on the FE properties, the polarization change was calculated as a function of strain applied isotropically along the $ac$-plane (Figure 7a). In addition, the magnetic spin structure with the lowest energy was evaluated for specific isotropic strain values of $-4\%$, $0\%$, and $4\%$, as well as for the experimental $a$- and $c$-lattice parameters (Table 1). Note that the experimental strain was consistent with our experimental results and anisotropic.

![Figure 7](image)

Figure 7. Theoretical calculations of the epitaxial strain dependence of ferroelectric and structural properties. a: Calculated polarization change along the $c$-axis as a function of isotropic strain in the $ac$-plane for BaCoF$_4$. b: Evolution of the lattice parameter as a function of strain. As the biaxial strain in the $ac$-plane increases, the $b$ lattice parameter decreases. c: Deviation from the bulk Co–F–Co angle value along the $a$-axis as a function of the $ac$-plane epitaxial isotropic strain.

Table 1. Magnetic Moment per Formula Unit (or Co Atom) along Each Axis ($a$, $b$, and $c$) for Each Magnetic Ordering Where the $G_i$ Is the Main Collinear AF Order and $C_i$ and $F_i$ are the WAF and WFM Spin Orders, Respectively$^a$

$^a$All strains are isotropic in the $ac$-plane, except for the $1.2\%$ strain result which was calculated with strain applied only along the $c$-axis, per experimental results.

value of the isotropic epitaxial strain corresponding to the strain along the in-plane $c$-axis ($1.2\%$), a polarization value $P_c = 10.1 \mu\text{C/cm}^2$ was calculated, while in the case of the experimental anisotropic strain, the polarization gives $P_c = 16.8 \mu\text{C/cm}^2$ (not shown in Figure 7a). This demonstrates the sensitivity of the FE polarization to the direction and sign of the strain. Figure 7b shows that the $b$-lattice parameter decreases as $a$ and $c$ increase, as expected from Poisson’s ratio. Note that in the experiments a slight decrease of the lattice parameter $a$ was found, which indicates that the in-plane strain was actually anisotropic.

The bulk crystal structure of BaCoF$_4$ contains CoF$_6$ octahedra zigzag chains along the $c$-axis (the Co–F–Co bonding angle is $\gamma = 146.5^\circ$) and nearly linear Co–F–Co chains along the $a$-axis ($\gamma = 173.7^\circ$), with BaCoF$_4$ puckered sheets stacked along the $b$-axis (Figure 1a). Figure 7c shows the modulation $\Delta \gamma$ of the calculated Co–F–Co bonding angle along the $a$-axis as a function of the isotropic strain. As discussed below, this bonding angle modulation should affect the magnetic spin structure.

Noncollinear magnetism was studied assuming B-phase AF ordering as the magnetic structure in BaCoF$_4$; however, the following results should apply to both A and B phases (see the Supporting Information).

A secondary AF ordering along the $b$-axis in the form of canted spins [weak antiferromagnetic (WAF) order] (Figure 1c, middle) is allowed within the theoretical ground state, in addition to the main collinear AF order along the $c$-axis. Similar findings have been reported by Ederer and Spaldin for BaNiF$_4$. By denoting the WAF and collinear magnetic orders as $C_i$ and $G_i$ respectively, we found that $G_iC_i$ is the ground state in the bulk BaCoF$_4$ (Figure 1c, middle). Note that the absolute magnitude of the canted (WAF) moment projection onto the $b$-axis alternates between two values, when followed along the $c$-axis. For the strain in our experiments, we calculated the canted moments to be 0.051 and 0.124 $\mu_B$ per formula unit (Table 1). This is explained by different octahedral tilts about the $a$-axis in adjacent corner-sharing CoF$_6$ octahedra with respect to the $ac$-planes. Using the strain value of our samples, the calculated corresponding angles were $24.0^\circ$ and $57.1^\circ$. Magnetic moments associated with different spin orderings and strain values are listed in Table 1.

Our results are in good agreement with the previously reported calculated spin structure of BaNiF$_4$ where a Dzyaloshinskii-Moriya (DM) interaction was shown to induce WAF canting along the $c$-axis in addition to the bulk collinear AF spin order along the $b$-axis. By choosing the same magnetic sites (Figure 1c, left) as for the case of BaNiF$_4$ we obtain for the case of BaCoF$_4$ the AF vectors $L_i = s_1 - s_2 - s_3 + s_4$ and $L_0$.
ordering is much smaller in magnitude, ranging from 0.006 to 0.1 meV/formula unit. On the other hand, the WFM configuration is energetically unfavorable for +4% or −4% strain and only slightly favorable (by 0.01 meV/formula unit) for the relaxed theoretical cell. Therefore, the anisotropic strain along the c-axis causes the transition between the $G_cC_b$ and $G_cC_bF_a$ states.

In order to determine whether the hypothesis of three subsequent magnetic phase transitions is viable, further experimental TRM curves were measured (Figure 8). In order to make the lowest temperature WFM spin phase ($G_cC_bF_a$) visible in the experiments, the sample was cooled in a 1 kOe field applied only for $T < T_{C1} = 19$ K after zero-field cooling to $T_{C3}$. The corresponding TRM curve (Figure 8, red circles) shows a magnetization decrease at $T_{C1}$. Since the magnetic phase above $T_{C1}$ was cooled in zero-field, and the coercive field for the $G_cC_b$ phase was larger than 1 kOe for $T < T_{C3}$, the corresponding WAF spin order phase ($G_cC_b$) at $T_{C1} < T < T_{C2}$ was not magnetized. In order to magnetize only the WAF phase ($G_cC_b$) below $T_{C2} = 41$ K, 1 kOe was applied while cooling down to 23 K, and then the field was turned off while cooling down further to 5 K. The corresponding curve (Figure 8, blue triangles) shows only the transition corresponding to WAF ($G_cC_b$) order. If the low temperature WFM spin order $F_a$ phase had been coupled to the WAF spin order phase $C_b$, the FC procedure would have revealed an additional magnetization decrease below $T_{C1} = 19$ K, but this was not the case. Finally, a simple FC down to 5 K in 1 kOe yielded the TRM curve (Figure 8, black squares) representing the sum of both transitions.

Finally, the question remains of why the transition from a collinear AF bulk phase $G_c$ to the WAF (in theory) $G_cC_b$ phase causes an observable response in the uncompensated magnetization (Figures 6b and 8), when the $G_cC_b$ state is nominally antiferromagnetic. We suggest that growth-induced defects are responsible for the distorted spin compensation when the spin phase is WAF $G_cC_b$. We note that in antiferromagnets with structural disorder, the TRM response usually has a WFM signal due to uncompensated moments at domain boundaries or piezomagnetism.47-49 It is also not uncommon for materials with collinear AF spin order in the bulk form to show WFM uncompensated moments when grown in thin film form.50-55 Here we observe a similar situation, though more complicated: growth defects distort the absolute spin compensation in the

*All strains are isotropic in the ac-plane, except for the 1.2% strain which was calculated with strain applied only along the c-axis, per experimental results. The large difference for the experimental strain value is likely due to the anisotropic strain.
WAF phase $G_{c}C_{b}$ that can cause the exchange interaction strength to fluctuate slightly throughout the film volume. Therefore, a weak uncompensated moment is observed ($\approx 0.01 \mu_{B}$ per magnetic ion, compared to the WAF moment $\approx 0.1 \mu_{B}$ in Table 1).

4. CONCLUSIONS

BaCoF$_4$ thin films were synthesized for the first time. The films were grown with the single out-of-plane orientation of the $b$-axis and with three in-plane domains with their polar $c$-axes rotated at $120^\circ$ with respect to each other. Due to the lattice mismatch with the (0001) Al$_2$O$_3$ substrates, the corresponding out-of-plane $b$-axis and in-plane $a$-axis lattice parameters were smaller than in the bulk, while the in-plane $c$-lattice parameter, representing the polar axis, was larger than in the bulk.

FE field switching was observed in BaCoF$_4$ thin films at both room temperature (using PFM) and at low temperatures (using remanent hysteresis loops). The PFM data were consistent with the three in-plane structural domains with the polar $c$-axis oriented at $120^\circ$ with respect to each other, observed using XRD. The PFM data also revealed that different regions had different fields at which their polarizations could be reversed.

A broad peak in the magnetic susceptibility was observed close to the Néel temperature of the bulk BaCoF$_4$ compound; however, additional WFM responses were found at temperatures below $T = 19$ and 41 K. The maximum measured WFM moment was 0.03 $\mu_{B}$ per formula unit. Strong magnetic fields up to 30 kOe were required to saturate WFM loops at $T = 5$ K, thus demonstrating the AF nature of the magnetic interactions.

First-principles calculations were used to study the magnetic and FE properties of the BaCoF$_4$ as a function of the $ac$-plane epitaxial strain. The calculations indicated the existence of a nonlinear polarization-strain coupling, suggesting a second-order piezoelectric response. An enhancement of the polarization was observed for nonzero strain values. For the value of epitaxial strain corresponding to the real thin films, a noncollinear ground state was found, with two additional WAF and WFM canted orders along the $b$- and $a$-axes, respectively. The sequence of magnetic transitions, $G_{c}C_{a}F_{b} \Rightarrow G_{c}C_{b} \Rightarrow G_{c}$, was predicted to take place with increasing temperature, starting from the magnetic ground state $G_{c}C_{a}F_{b}$. This result was consistent with the magnetic transitions found in the experimental TRM data.

Structural and magnetic data for samples intentionally grown with incorrect stoichiometry are presented and discussed. Figures S1 and S2 show the grazing XRD data for samples grown with BaF$_2$ and CoF$_2$ in 2:1 and 2:3 molar ratios, respectively. Figures S3 and S4 show the corresponding TRM curves for the 2:1 and 2:3 molar ratio samples. The computational results of possible collinear magnetic orderings of BaCoF$_4$ are discussed. Figure S5 shows the possible collinear orderings and the magnetic cell used for computation.
