LIFETIME AND HYDROGEN CROSS SECTION OF K⁻ MESONS

Bruce Cork, Glen R. Lambertson, Oreste Piccioni, and William Wenzel

January 30, 1957

Printed for the U.S. Atomic Energy Commission
In the course of experiments requiring the detection of antiprotons in a negative external beam from the Bevatron, it was found that $K^-$ mesons also could be distinguished from the large background of lighter charged particles, primarily $\pi^-$ mesons. Particles of a fixed momentum emitted in the forward direction from an internal beryllium target were channeled by a series of focusing quadrupole magnets for a distance of 100 feet from the target. In this beam, particles of a given mass were identified by velocity. The momentum was defined by the internal magnetic field of the Bevatron and an external deflecting magnet; velocity was measured by time-of-flight coincidence of six scintillation counters approximately equally spaced over the last 60 feet of the beam channel.

With particles of momentum of 0.9 Bev/c, the lengths of the delay cables on the time-of-flight coincidence counters were adjusted to produce a coincidence with particles of a selected velocity. Figure 1 shows the counting rate obtained for delays in a velocity range including particles of $K^-$ meson mass. The presence of $K^-$ mesons in the beam is clearly indicated. From the slope of the delay curve on either side of the "plateau" we estimate an upper limit of 5% for the contamination of the $K^-$ beam when the delays are set for the edge of the plateau.

In order to measure the $K^-\to p$ total cross section, a 62-inch long liquid hydrogen target was located after the last scintillator, $F$, of the time-of-flight selection system, Fig. 2. Beyond this, at a distance of 13.4 feet from $F$, a 13-inch-diameter scintillation counter, $L$, detected those particles which passed through the hydrogen target without interaction or decay. This counter was large enough to include the effects of the natural beam divergence and of the multiple Coulomb scattering in the hydrogen target.

---

* On leave from Brookhaven National Laboratory.
In principle, the change in transmission resulting from filling the hydrogen target is a measure of the total cross section; several corrections must be considered in this calculation, however. A large fraction of the $K^-$ mesons (approximately 40%) decays in the interval from $F$ to $L$. Decay secondaries that originate in the region ahead of the hydrogen target are only slightly attenuated in the hydrogen, and since only about 1% of these secondaries are detected by $L$, the net effect of decay ahead of the target is negligible in the transmission difference. In the region after the target, the rate of decay of $K^-$ mesons is increased by the energy loss in the hydrogen when the target is full. The apparent decrease in transmission from this cause requires a calculated correction of 6% in the cross section. Charged secondaries from interacting $K^0$s could occasionally be detected by $L$; this effect is small because of the "good" geometry of $L$ and the relatively low center-of-mass velocity in the $K^- - p$ interaction. The correction to the cross section required by this effect is estimated to be about 1%, and has been neglected.

After correction for the difference in decay in flight between the target and $L$, the value of the $K^- - p$ cross section computed from the observed transmissions is

$$
\sigma_T = 52 \pm 9 \text{ mb}.
$$

The indicated error is statistical only. Using the measured $\pi^- - p$ cross section, we compute that a 5% contamination of the beam by $\pi^-$ mesons would require that this value be increased by 1 mb. The correction for forward scattering into counter $L$ is less than 1 mb and has been neglected.

The $K^-$ lifetime may to a first approximation be calculated from the observed transmission $t_0$ measured by $L$ with no hydrogen in the target, i.e.,

$$
t_0 = e^{-d/\lambda},
$$

where $d$ is the separation of counters $F$ and $L$, and $\lambda$ is the mean decay distance related to the mean life $\tau$ by

$$
\lambda = c \tau \frac{Pc}{Mc^2},
$$

where $c$ is the velocity of light and $P$ and $M$ are the momentum and the mass,
respectively, of the K meson. Several corrections are necessary. Because
the empty hydrogen target was in place during the measurement, a correction
must be made for attenuation in the windows and insulation of the target. This
factor had been measured for antiprotons, for which the transmission was 0.90.
Taking into account the relatively larger cross section for the interaction of anti-
protons in matter at this momentum, we estimate the transmission for K mesons
of the empty target at 0.95 ± 0.02. Counters L and F will detect the K decay
products with a probability that depends on the kinematics of the decay and the
position along the beam where the decay occurs. Since Counter L is larger than
Counter F, this correction is equivalent to a reduction of the effective value of d.
With the assumption that the decay modes are the same for the K meson, we compute
a correction for this effect of 9% to the counting rate of L and 3% to the rate of F. Therefore,
we have made a net correction of -6% to the observed transmission. The uncertainty in the mean life from counting
statistics is ± 13%, and an additional uncertainty of ±0% comes from the possible
contamination due to mesons. The uncertainty in the K momentum contributes
± 5%. Combining the uncertainties, we find for the mean life of the K meson

\[ \tau = 14.9 \pm 2.2 \times 10^{-9} \text{ sec}. \]

Ioffe et al. \(^6\) obtain 9.5 ± 3.6 \times 10^{-9} \text{ sec}, and a later measurement \(^7\) gives
10.2 ± 3.1 \times 10^{-9} \text{ sec} for the mean lifetime of the K meson measured in emulsion
experiments performed at a distance of one to two mean lives from the target.
Because our experiment was performed at a distance of four mean lives from the
target, our greater value for the measured mean life is in the direction expected
if there is a long-life component in the K decay. However, the uncertainties are
such that both K lifetime measurements are consistent with a single value for the
K lifetime of 12 or 13 \times 10^{-9} \text{ sec}, or about the same as that obtained for the
K lifetime. \(^8\)

From the measured K mean lifetime and the observed yield (Fig. 1) of K mesons relative to at Counter F, we find that the ratio of K mesons to \(\pi\) mesons produced with momentum 0.9 Bev/c in the forward direction by 6-Bev
protons on a 6-inch beryllium target is about 1 to 150.
LEGENDS

Fig. 1. Delay curve of time-of-flight selector at 0.9 Bev/c. Calculated delays for \(\pi^-\) mesons, \(K^-\) mesons, and antiprotons are shown on the horizontal axis. Coincidence \(C_1C_2\) is made between the outputs of the two threefold coincidence circuits.
