Transverse momentum and centrality dependence of high-\(p_T\) non-photic electron suppression in Au+Au collisions at \(\sqrt{s_{NN}} = 200\) GeV

The STAR collaboration at RHIC reports measurements of the inclusive yield of non-photonic electrons, which arise dominantly from semi-leptonic decays of heavy flavor mesons, over a broad range of transverse momenta ($1.2 < p_T < 10$ GeV/c) in $p+p$, $d+Au$, and $Au+Au$ collisions at $\sqrt{s_{NN}} = 200$ GeV. The non-photonic electron yield exhibits unexpectedly large suppression in central $Au+Au$ collisions at high $p_T$, suggesting substantial heavy quark energy loss at RHIC. The centrality and $p_T$ dependences of the suppression provide constraints on theoretical models of suppression.

High $p_T$ hadron production measurements at the Relativistic Heavy Ion Collider (RHIC) show a strong suppression of the single-particle inclusive yields in nuclear collisions [1, 2, 3]. The suppression is commonly thought to arise from partonic energy loss in dense matter due to induced gluon radiation [4], with its magnitude depending strongly on the color charge density of the medium. This makes it a sensitive probe of the matter created in heavy-ion collisions, where a quark-gluon plasma may form if sufficient energy density is achieved.

Charm and bottom quarks are produced dominantly through high-$Q^2$ partonic interactions. Heavy flavor cross-sections and $p_T$ spectra have been calculated at next-to-leading-order (NLO) for both $p+p$ and $A+A$ collisions [5, 6, 7], including nuclear matter effects [7]. Although pQCD calculations agree well with heavy quark production in collider experiments at higher $\sqrt{s}$ [8], they disagree with recent RHIC measurements [3, 10]. Nevertheless, measurements of heavy quark production potentially provide new constraints on partonic energy loss mechanisms [11, 12, 13, 14, 15, 16, 17]. Gluon radiation in a forward cone is suppressed for heavy quarks at moderate energy (dead cone effect) [11, 12], with corresponding reduction in medium induced energy loss and less suppression of heavy-quark mesons than light quark mesons.

Direct reconstruction of heavy flavor mesons via hadronic decay channels [1] is difficult in the complex environment of high energy nuclear collisions. Heavy quark production can also be studied through measurements of electrons (positrons) from semileptonic $D$ and $B$ decays. This Letter reports STAR Collaboration measurements of the non-photonic electron yield, $(e^+ + e^-)/2$, in $p+p$, $d+Au$, and $Au+Au$ collisions at nucleon-nucleon center of mass energy $\sqrt{s_{NN}} = 200$ GeV. The data extend significantly the $p_T$ range of previous electron suppression studies [18], to a region of phase-space where bottom decays are expected to be dominant. Large differences in energy loss are expected between $c$ and $b$ quarks in this region [14], and these measurements provide important new constraints on partonic energy loss mechanisms.

STAR is a large acceptance apparatus comprising several detector subsystems within a 0.5 T solenoidal magnet field [19]. The main detectors for this analysis are the Time Projection Chamber (TPC) [20] and the barrel Electromagnetic Calorimeter (EMC) [21]. The EMC has a gas-filled Shower Maximum Detector (SMD) at a depth of $\sim 5X_0$ to measure shower shape and position. A fast trigger based on single EMC tower energy enriches the electron sample at high $p_T$. Electrons at moderate $p_T$ were reconstructed from minimum bias and centrality triggered Au+Au event samples, while EMC triggered events were used for $p_T > 3 - 4$ GeV/c. Au+Au data were divided into 3 centrality classes based on the track multiplicity measured at midrapidity. The integrated luminosity sampled by the EMC trigger is 100 nb$^{-1}$ for $p+p$, 370 μb$^{-1}$ for $d+Au$ and 26 μb$^{-1}$ for the most central $Au+Au$ events. The charged particle acceptance is $0 < \eta < 0.7$ and $0 < \phi < 2\pi$, selected to minimize the radiation length of detector material interior to the EMC within the available EMC acceptance.

The analysis has three main steps: selection of electrons; subtraction of background from decays and interactions in material; and residual corrections to the signal yield. Table I shows the major correction factors and uncertainties, which we now discuss in detail.

**Electron PID:** Electron identification utilizes ionization energy loss ($dE/dx$) and track momentum from the TPC, together with energy and shower shapes from the EMC. Tracks with momentum $p > 1.5$ GeV/c are accepted if they originate from the primary vertex (distance of closest approach less than 1.5 cm) and project to an active EMC tower, with acceptance $\alpha_{EMC} \sim 75 - 85\%$ of the EMC instrumented coverage. This reduced acceptance is due to dead or noisy electronics channels. Initial electron identification is based on $p/E < 2$, where $p$ is the TPC track momentum and $E$ is the energy of the EMC tower. Simulations show that this cut excludes $\sim 7\%$ of real electrons due to sharing of shower energy between towers. Additional hadron rejection is based on the shower shape measured by the SMD. Figure I shows the $dE/dx$ distribution for tracks passing the $p/E$ and shower shape cuts. The curves show Gaussian functions fit to the distribution, representing the yields of $p + K$, pions and electrons [22]. The parameters in the fit are the yields, widths, and overall $dE/dx$ scale, with widths and the distances between centroids being quasi-free parameters, constrained by a model of energy deposition in the TPC gas [23].

Electrons are selected by cutting on TPC energy loss $dE/dx_{min} < dE/dx < 5.1$ keV/cm. $dE/dx_{min}$ is around 3.5 keV/cm, with the specific value having weak dependence on the event multiplicity and increasing slowly with track momentum, to optimize electron efficiency and hadron rejection while preserving more than 50% of the electrons in the $dE/dx$ distribution. The residual hadron background satisfying the $dE/dx$ cut is estimated based on Gaussian fits similar to those in Figure I.

Table I shows the combined electron tracking and identification efficiency (‘‘PID efficiency’’), determined by

embedding simulated electrons into real events. It is significantly below unity due to tracking efficiency (∼70%), exclusion of electrons due to the energy leakage to neighboring towers, and SMD response. Its increase from $p_T = 2$ to 8 GeV/c is due to increasing SMD efficiency.

**Electron background:** Background from photonic sources is due largely to photon conversions (∼85%) in the detector material between the interaction point and the TPC ($X/X_0 ∼ 4.5\%$) and $\pi^0$ and $\eta$ Dalitz decays (∼15%). The photonic electron yield is measured using the invariant mass distribution of track pairs detected in the TPC. One track of the pair is required to fall in the EMC and SMD cuts. The lines are Gaussian fits for $p + K$, $\pi$, and electron yields. (b) Invariant $e^+e^-$ mass spectrum. (c) Ratio of inclusive and background electron yield vs. $p_T$ for $p+p$ and Au+Au collisions. Vertical bars are statistical errors, boxes are systematic uncertainties.

The shaded region in Figure 1 is the difference between the opposite and same-sign distributions and represents the photonic yield. It exhibits a peak at zero invariant mass due to conversions, and a tail at non-zero mass due to Dalitz decays [24]. Selecting $m < 150$ MeV/$c^2$ accepts ∼98% of all $\pi^0$ and $\eta$ Dalitz pairs in this distribution. The efficiency $\varepsilon_B(p_T)$ to identify a photonic electron in the EMC by this procedure was estimated by embedding [23] the main background sources ($\pi^0$ and $\gamma$) with a realistic momentum distribution derived from recent RHIC data [26] into real events.

The photonic electron yield $N_{ph}$ is calculated in each $p_T$ bin via $N_{ph} = (N_{unlike} - N_{like})/\varepsilon_B$. Additional background, mainly from $\omega$, $\phi$, and $\rho$ decays, was estimated using PYTHIA [27] and HIJING [28] simulations to be ∼2–4% of $N_{ph}$ [9] and is included in the systematic uncertainty of $N_{ph}$. Figure 1I depicts the ratio of the inclusive to the photonic electron spectra for $p+p$ and Au+Au collisions. The Figure shows a clear electron excess. Within uncertainties, the non-photonic excess is independent of centrality at high $p_T$.

**Non-photonic electron yield:** The trigger efficiency was determined by comparing the electron candidate spectrum in the minimum bias and triggered data sets. At high-$p_T$ the ratio of the spectra is compatible with the online scale-down factor applied to minimum bias events. The non-photonic spectrum is the difference of the inclusive to the photonic electron spectra for $p+p$ and Au+Au collisions. The Figure shows a clear electron excess. Within uncertainties, the non-photonic excess is independent of centrality at high $p_T$.

**Systematic uncertainties:** Systematic uncertainties were determined by varying cut parameters within reasonable limits. The uncorrected systematic uncertainty of the electron yield is dominated by the electron identification efficiency and photonic background reconstruction at low $p_T$ and the correction for residual hadron background at high $p_T$.

Figure 2 shows the fully corrected non-photonic electron spectra for 200 GeV $p+p$, $d+Au$, and Au+Au collisions. The curves correspond to FONLL (Fixed Order Next-to-Leading Log) predictions [1] for semileptonic $D$ and $B$ meson decays. The calculated spectrum is scaled by 5.5 (see below).
Figure 3 upper part (points), shows the ratio of measured to unscaled FONLL-calculated non-photonic electron yield for $p+p$ collisions. The calculation describes the shape of the measured spectra relatively well, though with a large difference in their overall scale. Better agreement is found at larger $\sqrt{s}$. The same ratio is shown for published STAR \cite{9} and PHENIX \cite{10} measurements. The horizontal dashed line is at $5.5 \pm 0.8$ (stat) $\pm 1.7$ (sys), corresponding to the ratio between the total charm cross section measured by STAR \cite{9} to the central value predicted by FONLL \cite{7,8}. The shaded band around that line shows the experimental uncertainty in this ratio. PHENIX data \cite{10} exhibit a lower ratio and appear not to be consistent with the data reported here. The lower part (curves) shows the relative contribution to the FONLL calculation of charm and bottom decays, with the variation due to NLO uncertainties \cite{7,29}. The $B$-decay contribution is expected to be significant in the upper $p_T$ range of this measurement.

Modification of the inclusive particle production is measured by the nuclear modification factor $R_{AA}(p_T)$ for $R_{AA}$ is unity for hard processes without nuclear effects. Figure 3 shows $R_{AA}(p_T)$ for non-photonic electrons in $d+Au$ and central $Au+Au$ collisions. Error bars show the statistical uncertainties, boxes show uncorrelated systematic uncertainties, and the filled band at unity is the overall normalization uncertainty. $R_{AA}$ for $d+Au$ is consistent with a moderate Cronin enhancement. $R_{AA} \sim 0.2$ for central $Au+Au$ collisions at $p_T > 3$ GeV/c, consistent with a previous measurement at lower $p_T$ \cite{18}. The suppression is similar to that for light hadrons at $p_T > 6$ GeV/c \cite{2}.

Figure 4 shows predictions for electron $R_{AA}$ from semi-leptonic $D$- and $B$-meson decay in central $Au+Au$ collisions using calculations of heavy quark energy loss.

Curve I uses DGLV radiative energy loss via few hard scatterings with initial gluon density $dN_g/dy = 1000$, consistent with light quark suppression. Curve II uses BDMPS radiative energy loss via multiple soft collisions \cite{15}, with transport coefficient $\hat{q}$. $\hat{q}$ is set to 14 GeV$^2$/fm, though light quark hadron suppression provides only a loose constraint $4 < \hat{q} < 14$ GeV$^2$/fm. Both calculations predict much less suppression than observed.

This discrepancy may indicate significant collisional (elastic) energy loss for heavy quarks. Curve III is a DGLV-based calculation including both radiative and collisional energy loss, together with path length fluctuations \cite{15}. The calculated suppression is also markedly less than that observed. For Curve IV, the heavy quark energy loss is due to elastic scattering mediated by resonance excitations ($D$ and $B$) and LO t-channel gluon exchange \cite{17}. This calculation also predicts significantly less suppression than observed.

Dead cone reduction of energy loss is expected to be more significant for bottom than charm quarks in the reported $p_T$ range. Curve V, which is the same calculation as curve II but for $D$-meson decays only, agrees better with the data. Since there is better agreement of data and theory for bottom than charm production at the Tevatron, the scale factor 5.5 between calculated and measured $p+p$ electron yields may overestimate the $B$ decay contribution at RHIC, i.e. $D$ decays may in fact dominate the electron yields in the reported $p_T$ range, favoring calculation V. A direct measurement of $D$-mesons at high-$p_T$ is required to understand energy loss of heavy quarks in detail. Finally, multi-body mechanisms may also contribute to heavy quark energy loss \cite{31}.

We have reported the measurement of high-$p_T$ non-photonic electrons in $p+p$, $d+Au$, and $Au+Au$ collisions at $\sqrt{s_{NN}} = 200$ GeV. A pQCD calculation for heavy quark
production in $p+p$ collisions underpredicts the data, although it describes the overall shape of the $p_T$ distribution relatively well. Large yield suppression is observed in central Au+Au collisions, consistent with substantial energy loss of heavy quarks in dense matter. The suppression is larger than that expected from radiative energy loss calculations, suggesting that other processes contribute significantly to heavy quark energy loss. This unique sensitivity to the energy loss mechanisms makes the measurement of heavy quark suppression an essential component of the study of dense matter. Full description of the interaction between partons and the medium will require further detailed measurements of charm and bottom separately.
