STUDY OF PION-PION RESONANCES IN 3.3 BeV \( \pi^- - p \) INTERACTIONS*

Zaven G. T. Guiragossian†

Lawrence Radiation Laboratory
University of California
Berkeley, California

April 22, 1963

We have studied the interactions

\[
\pi^- + p \rightarrow \pi^- + \pi^+ + n \quad (a)
\]

and

\[
\pi^- + p \rightarrow \pi^- + \pi^0 + p \quad (b)
\]

in the Lawrence Radiation Laboratory 72-in. Hydrogen Bubble Chamber exposed to a 3.3 ± 0.1 BeV/c \( \pi^- \) beam from the Bevatron. The beam momentum and uncertainty were determined by the measured momentum distribution of incoming tracks of length greater than 60 cm and proper entrance angles.

Data reduction was performed with the FOG CLOUDY FAIR system. With the above beam momentum and uncertainty, two-prong events were fitted to reaction types (a) and (b). Events with proper beam acceptance angles, converging iterations, and \( \chi^2 \) values ≤ 5.5 for either reaction were examined. Separation into reaction (a) or (b) was done by determining the ionization and range of the positively-charged tracks, up to 1.0 BeV/c momenta. The missing neutral masses were computed for both types by using measured parameter values. For the separated events, the distribution of missing mass squares of (a) gave a peak at the neutron mass and another near the \( (n + \pi^0) \) mass. For (b), we obtained a peak at the \( \pi^0 \) mass, and enhancement at the \( \eta \) mass. The missing mass squares were computed by

\[
M_0^2 = (E_{\pi^-} + M_p - E_{\pi^-} - E_{\pi^+, p})^2 - (P_{\pi^-} - P_{\pi^- - P_{\pi^+, p}})^2.
\]
Cuts were then imposed to define the desired neutral masses for the entire sample. Further, a "good measurement" criterion was applied to the entire data. Including 1700 elastic interactions, a total of 5000 two-prong events were measured. Thus, 532 events were identified as reaction (a) and 365 events as reaction (b); these include 30 half-weighted ambiguous events which had high momentum transfers to the nucleon.

Experimental Results. We have computed the "dipion" effective mass, \( \omega \), the invariant momentum transfer to the nucleon, \( t = \Delta^2/\mu^2 \), and the angle between the incoming and outgoing \( \pi^- \) in the barycentric system of the final pions, \( \Theta_{\pi\pi} \). The beam momentum uncertainty contributed approximately 15 MeV to the error in \( \omega \) and other errors brought this to about 35 MeV; accordingly we chose to histogram \( \omega \) in 50 MeV intervals. Figures 1(a) and 1(b) show the histogram of the "dipion" mass for the \((\pi^- \pi^+)\) and \((\pi^- \pi^0)\) states, respectively. The \((\pi^- , \pi^0)\) spectrum is strongly peaked at \( \omega_\pi = 775 \) MeV, which accounts for the \( \rho^- \) meson. The dashed curve in Fig. 1(b) represents the sum of 50% invariant phase space and 50% invariant phase space with a normalized Breit-Wigner resonance term of the form \( N/[(\omega-\omega_r)^2 + (\Gamma/2)^2] \). The resonance term used has a value of full width at half maximum \( \Gamma = 125 \) MeV. This curve is normalized to the \( \rho^- \) peak. The \((\pi^- , \pi^+)\) spectrum is also strongly peaked at a central value of \( \omega_\pi = 775 \) MeV, which accounts for the \( \rho^0 \) meson; however, here the resonance width appears to be broader than the width of the \( \rho^- \) meson. With the mixture of invariant phase space and phase space with resonance, determined by the \( \rho^- \) spectrum, the dashed curve in Fig. 1(a) is computed by using a value of \( \Gamma = 175 \) MeV. This curve fits best around the \( \rho^0 \) region and is normalized to the \( \rho^0 \) peak.
A second peak in the \((\pi^-,\pi^+)\) spectrum is observed with a central value \(\omega = 1250\) MeV and a width of \(\Gamma \approx 200\) MeV. Similar peaks have been seen in two recent experiments.\(^1\),\(^2\),\(^3\) The shoulder seen around 1050 MeV which appeared to be resolved at an earlier stage of this experiment has lost its resolution in this final analysis.

To study the resonant behavior of these peaks we have constructed distributions in \(\cos \Theta_{\pi\pi}\) for several segments of the \(\omega\) spectrum. Due to the \(\omega^2/\mu^2\) vs \(\Delta^2/\mu^2\) phase-space limitations, the angular distributions are presented with lower limits of \(t\) chosen as \(t_{\min} = 0\) for \(275 < \omega < 1000\) MeV, and \(t_{\min} = 4.0\ \mu^2\) for \(1000 < \omega < 1450\) MeV. Distributions were made in \(t\) for various segments of \(\omega\) in both reactions. All of these distributions showed a characteristic dependence \(t/(t + 1)^2\). Most of the events were confined to values below \(t = 25\ \mu^2\), the rest being dispersed in a tail extending to \(t_{\max} = 275\ \mu^2\). Accordingly, the angular distributions are presented with the upper limit of \(t = 20\ \mu^2\). Figure 2(a) is the angular distribution at the \(p^-\) resonance showing a characteristic \(\cos^2 \Theta\) dependence over a constant background, \(700 < \omega(\pi^-,\pi^0) < 850\) MeV. Figure 2(b) is the angular distribution above the \(p^-\) resonance, \(850 < \omega(\pi^-,\pi^0) < 1000\) MeV. The forward peak indicates that the p-wave phase shift \(\delta_1\), has crossed over 90°. Figure 2(c) shows that the angular distribution at the \(p^0\) resonance is strongly peaked in the forward direction, \(700 < \omega(\pi^-,\pi^+) < 850\) MeV. This behavior continues after the \(p^0\) resonance as seen in Fig. 2(d), \(850 < \omega(\pi^-,\pi^+) < 1000\) MeV. This indicates that an s-wave or a d-wave phase shift from the isotopic spin \(T = 0\) component of the \((\pi^-\pi^+)\) state is sufficiently strong to interfere with the p-wave phase shift of the \(T = 1\) component \(\delta_1\), such that it prevents the effective phase shift from reaching 90° at the \(p^0\) resonance. The \(T = 2\) component is ruled out for such a behavior since it would have appeared in both reactions.
Figures 2(e), (f), and (g) show the angular distribution before the peak, $1000 \leq \omega(\pi^-, \pi^+) < 1150$ MeV, at the 1250 MeV peak $1150 \leq \omega(\pi^-, \pi^+) < 1300$ MeV, and after the peak $1300 \leq \omega(\pi^-, \pi^+) < 1450$ MeV, respectively; Fig. 2(f) is a non-isotropic symmetric distribution. The 1250 MeV peak is seen in the $(\pi^-, \pi^+)$ state and not in the $(\pi^-, \pi^0)$, so that this resonance has isotopic spin $T = 0$; whereby, it is confined to even angular momenta. Although Fig. 2(f) does not show the characteristic d-wave hump at $\Theta_{\pi\pi} = 90^\circ$, the $J = 0$ value is ruled out by nonisotropy. Dalitz plots were constructed for reactions (a) and (b).

Figure 3 represents the projections of those plots in terms of the final pion reaction center of mass kinetic energies, $T_{\pi}$. The curves shown are the invariant phase-space integrals normalized to the total area of each histogram. The position of possible pion-nucleon resonances are indicated accordingly.

Figure 3 (a₁) and (a₂) are the $T_{\pi^+}$ and $T_{\pi^-}$ projections, which are equivalent to the $(\pi^-, n)$ and $(\pi^+, n)$ effective mass spectra, respectively. No appreciable deviation from phase space is seen in either state. Figure 3(b₁) and (b₂) are the $T_{\pi^-}$ and $T_{\pi^-}$ projections, giving the $(\pi^-, p)$ and $(\pi^0, p)$ effective mass spectra, respectively. Deviations from phase space are evident in both states. The $T_{\pi^-}$ distribution has a 4-standard-deviation peak corresponding to 2400 MeV(\pi^-, p) effective mass. The $T_{\pi^0}$ distribution has a 3.5-standard-deviation peak at the $N_{3/2}^*(1238)$ position. If the peak in the $T_{\pi^-}$ distribution is assumed to be due to the $N_{3/2}^*(1238)$ resonance, then the 2400 MeV peak in the $T_{\pi^-}$ distribution must be considered as spurious. An examination of the Dalitz plot of reaction (b) shows that 40% of the events at the 2400 MeV region of $T_{\pi^-}$ come from the $N_{3/2}^*(1238)$ of $T_{\pi^-}$, and 25% from the $\rho^-$ resonance.

In reaction (a) the final state $\pi^-\pi^-$ resonances dominate over $(\pi, n)$ interactions, whereas in reaction (b), with the presence of a single $\pi^-\pi^-$ resonance, the remaining phase space is available to the pions for any $(\pi, p)$ interactions.
Conclusion. The striking difference in the angular distribution between the \( \rho^0 \) and \( \rho^- \) needs further explanation. This difference seems to be independent of energy. If the apparent enlarged width of the \( \rho^0 \) is due to an adjacent \( \omega^0 \) production which decays electromagnetically into \( 2\pi^+ \)'s, then the same process cannot explain the forward peaking of the \( \rho^0 \) angular distribution for the following reason. In reaction (a), virtual \( \omega^0 \) production would be through a \( \rho^+ \) exchange, whereas a \( \rho^0 \) production proceeds through a \( \pi^+ \) exchange; it has been indicated that the \( \pi^-\pi^- \) angular distribution combined from both processes would still be symmetric and of the form \( a + b \cos^2 \Theta \).

Recent experiments of high energy \( p-p \) elastic scattering indicate that the first Pomeranchuk trajectory may have a slope of \( a_{P_1}^+ (0) = 1/80 \mu^2 \). If the Regge singularities are confined to simple poles and if a constant slope of Regge trajectories is assumed over a wide energy range, then the 1250 MeV \( T = 0 \pi^-\pi^- \) resonance can be interpreted as the physical manifestation of \( P_1 \). Recently, a second Pomeranchuk trajectory \( P_2 \), with the intercept value \( a_{P_2}^- (0) = 0.5 \), has been postulated. Under the above assumptions this should manifest itself as a \( T = 0 \pi^-\pi^- \) resonance at 1800 MeV, which is above the phase-space limitations of this experiment.

I am grateful to Prof. Wilson M. Powell for his support and encouragement and to Dr. Robert W. Birge for numerous discussions and guidance. This experiment would not have been possible without the efforts of many in the Powell-Birge research group. I would like to thank Prof. Luis W. Alvarez and his group for the bubble chamber exposure, and the data analysis group of Howard White for the data reduction.
