Anxiolytic Effects of Music Interventions in Patients Receiving Incenter Hemodialysis: A Systematic Review and Meta-Analysis

Lorraine S. Evangelista  
Yong-Gyu Park

Hemodialysis (HD) is the most common renal replacement therapy to maintain the lives of patients with end stage renal disease (ESRD) (United States Renal Data System [USRDS], 2014). Yet patients requiring maintenance HD often have a negative perception of HD treatment. A patient who participated in a study by Hagren, Pettersen, Severinsson, Lützén, and Clyne (2001, p. 199) astutely named HD his “other job” because he spent at least four hours, three times a week receiving HD treatments, as well as extra hours traveling to and from the HD center, waiting for the machine at the center, and undergoing post-HD care (e.g., vascular access site hemostasis, weighing post-HD) (Hagren et al., 2001). Patients have negatively described their time spent in HD treatment as not worthwhile (Moran, Scott, & Darbyshire, 2009). They also often report psychological symptoms, such as anxiety, stress, depression, and a low quality of life (Feroze et al., 2012; Feroze, Martin, Reina-Patton, Kalantar-Zadeh, & Kopple, 2010).

Anxiety is a common emotion affecting patients on maintenance HD (Cukor et al., 2008; Janiszewska, Lichodziejewska-Niemierko, Golebiewska, Majkowicz, & Rutkowski, 2013). Patients may experience anxiety because of anticipation of the treatment, feelings of stress, loss of control, or potential risk of complications (Gillen, Biley, & Allen, 2008). Anxiety is a state manifesting as apprehension, discomfort, and tension (American Psychiatric Association [APA], 2013; Spielberger, 1972). Anxiety can be divided into state and trait anxiety; state anxiety is characterized by feelings of worry, nervousness, and muscle tension when confronting a stressful situation, whereas trait anxiety reflects a personal tendency in terms of responding to stressful situations (Spielberger, 1972). It is important to manage anxiety because

Objectives
1. Discuss the impact anxiety has on patients requiring maintenance hemodialysis.
2. Explain the positive effects of music intervention for patients experiencing anxiety while on hemodialysis as outlined in this current study.
3. List the rationale for future research regarding music intervention with patients being treated for end stage renal disease with hemodialysis.

Goal
To identify the methodological quality and examine the effectiveness of music interventions on anxiety in patients requiring maintenance hemodialysis.

Key Words: Anxiety, hemodialysis, meta-analysis, music intervention, systematic review.

Music interventions are effectively used to reduce anxiety in patients on maintenance hemodialysis (HD). The purpose of this review was to identify the methodological quality and examine the effectiveness of music interventions on anxiety in patients requiring maintenance HD. Articles were searched through 10 electronic databases, and relevant articles were systematically reviewed. Seven studies were analyzed for this study, and the combined seven studies revealed a medium effect size (pooled standardized mean differences [SMD] = 0.76; 95% CI: 0.55, 0.98). This study found that music interventions effectively reduce anxiety in patients on maintenance HD.

Anxiolytic Effects of Music Interventions in Patients Receiving Incenter Hemodialysis: A Systematic Review and Meta-Analysis

Untreated anxiety correlates with negative outcomes, such as reduced quality of life, poor adherence to HD treatment, and increased mortality (Birmelé, Le Gall, Sautenet, Aguerre, & Camus, 2012; Cukor et al., 2008; Johnson & Dwyer, 2008).

Various studies on anxiety reduction have been done using pharmacological and non-pharmacological methods. Pharmacological methods using sedatives or anti-anxiety medicines may have side effects (Beathard, Urbanes, Litchfield, & Weinstein, 2011). Consequently, alternatives to the pharmacological methods, such as music intervention, relaxation techniques, and hypnosis, have been introduced (Cantekin & Tan, 2013; Mahdavi, Gorji, Gorji, Yazdani, & Ardebil, 2013; Pyo, 2011; Untas et al., 2013). Music interventions, which are non-invasive and non-pharmacological approaches, are widely used for patients to reduce anxiety while waiting for surgeries and various procedures, such as coronary angiography (Kemper & Danhauer, 2005; McDonald, Zauszniewski, Bekhet, Dehelian, & Morris, 2011; Moradipanah, Mohammadi, & Mohammadi, 2009; Pittman & Kridli, 2011). Music interventions can be defined as “listening to music through music device or live music” (Chan, Wong, & Thayala, 2011, p. 334). Music interventions are also effectively used to improve psychophysiological signs and symptoms among patients on maintenance HD. They decrease anxiety in patients on maintenance HD (Cantekin & Tan, 2013; Kim, Lee, & Sok, 2006; Pothoulaki et al., 2008) because music acts as relaxation and diversion to others (Colwell, 1997).

Although there are a number of studies on using music interventions in reducing anxiety, they vary in terms of characteristics of the music interventions (e.g., type, frequency, dose, and/or interval of music interventions) and methodological quality, which may confound scientific research in this area.

A systematic review and meta-analysis synthesizing multiple relevant studies can provide a useful guide for clinical decisions (Garg, Hackam, & Tonelli, 2008; Glass, McGaw, & Smith, 1981). However, despite its potential benefits, to date, there has been no systematic review of research studies that used music interventions for anxiolytic effects in patients on maintenance HD. Thus, the present study aims to systematically review research studies that used music interventions in this specific area and identify the effects of music interventions. The specific purposes of the study were to 1) investigate the overall characteristics of music interventions, 2) identify the methodological quality of research involving the use of music interventions, and 3) examine the effectiveness of music interventions on anxiety in patients requiring maintenance HD. This systematic review and meta-analysis provides information to better understand the impact of music interventions on reducing anxiety in patients on maintenance HD.

**Methods**

**Inclusion and Exclusion Criteria for Literature Search**

To identify study eligibility of this systematic review, the PICO (participants, intervention, comparison, and outcomes) framework was used. Experimental studies with randomized or clinical controlled trials that involved both treatment and control groups were included. Observational studies and intervention studies without control groups were excluded. Target populations (P) were adult patients 18 years and older on maintenance HD. Intervention (I) was defined as music therapy provided during HD, and comparison (C) was defined as routine HD. The principal outcome (O) was state anxiety measured by the State Anxiety scale of the State-Trait Anxiety Inventory (Spielberger, Gorschuch, Lushene, Vagg, & Jacobs, 1983). Studies were excluded when the primary outcomes were something other than state anxiety, or anxiety was not measured by Spielberger’s state anxiety scale. No restrictions on publication time period and language were imposed. The included setting was incenter HD.

**Search Methods**

Articles were searched in January 2014 through 10 electronic databases: Cochrane Library, Cumulative Index to Nursing & Allied Health Literature (CINAHL), EMBASE, Medline, PubMed, and five Korean databases (KMbase, KoreaMed, Korea National Assembly Library, National Discovery for Science Leaders [NDSL], and RISS4U). Unpublished master’s theses or doctorate dissertations were included. Other articles were found from reviewing references of relevant full-text manuscripts on similar topics.

**Study Data Extraction**

All searched articles from the 10 databases were reviewed and extracted by two reviewers (investigators YK and YP). The reviewers selected studies by reviewing titles and abstracts based on the predefined selection criteria after excluding duplicated studies. Subsequently, the reviewers extracted the final studies by reading the full text of the articles. The study extraction processes and the final studies were reviewed and confirmed by all reviewers.

**Data Analysis and Quality Assessment**

**Characteristics of the included studies.** Study characteristics were analyzed under the categories of type, frequency, dose, duration, and outcome of music intervention in the treatment group. The characteristics of the control group were also analyzed.

**Methodological quality assessment.** A study quality assessment was performed by two investigators (YP & YK) and confirmed by the other investigator (LSE) using the Quality Assessment Tool for Quantitative Studies (QATQS) [National Collaborating Centre for Methods and Tools, 2008; Thomas, Ciliska, Dobkins, & Micucci, 2004]. The reviewers evaluated study quality independently using the QATQS criteria and a user’s guide-
line called a QATQS dictionary. Six components (selection bias, study design, confounders, blinding, data collection methods, and withdrawals/dropouts) were rated as strong, moderate, or weak. In addition, intervention integrity (e.g., percentage of participants receiving the allocated intervention or exposure of interest) and analysis (e.g., use of appropriate statistical methods) were evaluated using multiple choice answers.

If there were no clear data on study methodology, data were obtained by emailing the primary study author. The two reviewers compared their individual assessment results. Discrepancies between the reviewers were resolved by discussion to reach an agreement.

Measurement of Treatment Effect and Assessment of Heterogeneity/Publication Bias

Meta-analysis was performed using the Cochrane Review Manager (RevMan) version 5.2 (The Cochrane Collaboration, The Nordic Cochrane Centre, Copenhagen, Denmark). Standardized mean differences (SMD) were used for the effect size of anxiety, and 95% confidential intervals (CI) were computed to report the significance of the effect size. Cohen (1988) suggested criteria for interpreting effect sizes; small, medium, and large effect sizes are 0.20, 0.50, and 0.80, respectively.

Levels of heterogeneity were evaluated using a Q-statistic and I-squared (F) test (Higgins & Thompson, 2002). I-squared test results of about 25%, 50%, and 75% indicate low, moderate, and high heterogeneity, respectively (Borenstein, Hedges, Higgins, & Rothstein, 2009; Higgins & Green, 2011). In order to obtain the pooled SMD estimate and its 95% CI, a fixed effects model rather than random effects model was used because of absence of heterogeneity. In addition, a funnel plot was created to evaluate possible publication bias; symmetry in the plot signifies a low possibility of publication bias.

Results

Study Selection

Figure 1 illustrates the process of searching relevant articles for the present meta-analysis. The study search initially yielded 384 articles from 10 electronic databases and reference review from relevant full-text manuscripts. One hundred forty duplicated articles were excluded. The titles and abstracts of 247 articles were reviewed, and 226 articles were then excluded because of an irrelevant study population (no patients on chronic HD), study design (no RCT or CCT using music interventions), or outcome (not anxiety). Subsequently, 21 full-text articles were evaluated for eligibility, and 14 articles were excluded again, namely studies having no control group, studies having different outcomes (stress, depression, etc.), and a duplicate study. Finally, a total of seven studies were included in the meta-analysis. The seven selected studies were reported in English or Korean between 1996 and 2013. Five studies were conducted in Korea (Choi, 1996; Chung, 2004; Kim et al., 2006; Lim, 2004; Pyo, 2011), one in Greece (Pothoulaki et al., 2008), and one in Turkey (Cantekin & Tan, 2013).

Study Characteristics and Nature of Music Interventions

Table 1 shows the characteristics of the included studies. Three studies (42.9%) were published, and four studies (57.1%) were unpublished master’s theses or doctoral dissertations. A total of 351 patients on maintenance HD participated in the seven studies: 176 patients were in the treatment group, and 175 patients were in the control group. All study participants in the treatment group had music interventions during their HD treatment, while the participants in the control group received routine HD care.

Six studies provided pre- and patient-selected music. For all interventions, the patients individually listened to music from pop, native, gospel, classical, culturally based, jazz, film soundtracks, or new age music genres on pre-recorded tapes, compact discs (CDs), or MP3 players during HD. The length and duration of the music interventions varied; 30 to 180 minutes of music interventions were delivered, but most interventions involved 30 to 60 minutes of music interventions per HD treatment session for 1 to 3 weeks (see Table 1). None of the studies used live music or indicated that they used certified music therapists for the music interventions.

Study Outcomes

Table 2 shows the outcomes of the included studies. Six studies (85.7%) reported a significantly decreased state anxiety after the music intervention. In one study, state anxiety had decreased after three weeks of music intervention, but the change was not statistically significant (p = 0.36) (Choi, 1996). Other outcomes, such as depression, perceived psychological stress, immune function, pain, blood pressure, and/or boredom, were also analyzed. Four out of five studies showed significant decreases in depression. Perceived psychological stress and boredom were found to be significantly lower after music interventions in two studies and one study, respectively.

Methodological Study Quality Assessment

Table 3 displays the results of our methodological quality assessment using the QATQS and the QATQS dictionary (user’s guide). Six studies (85.7%) were rated “moderate” for selection bias, which assesses sample representativeness of the target population and percentages of selected individuals that agreed to participate in the study. All seven studies were rated “strong” for study design, which requires either randomized clinical trials or clinical controlled trials. Five studies were rated “moderate” for confounders, which evaluates percentages of relevant confounders that were controlled. All studies were rated “weak” for blinding, which examines blinding of the outcome to assessors and partic-
Participants. All studies were rated “strong” for data collection methods, which identifies reliable and valid tools for primary outcomes. Five studies were rated ‘moderate’ for withdrawals/dropouts, which evaluates reports of the percentage of participants that completed the interventions.

Besides the six rating components, an evaluation of intervention integrity and analysis was performed. Six studies reported that 80% to 100% of participants received the allocated intervention or exposure of interest, while one study did not report this information (Intervention integrity). All seven studies used appropriate statistical methods (Analysis).

### Music Intervention Effects on Anxiety and Publication Bias

The heterogeneity test indicated no significant differences across the studies (Cochrane’s $Q_{[Chi-squared, p = 0.62]}; I^2 = 0\%$), and thus, the fixed effects model was used for pooled estimates. Figure 2 shows the music intervention effects; the combined seven studies revealed a medium effect size (pooled SMD = 0.76; 95% CI: 0.55, 0.98), indicating that music intervention across the seven studies effectively improved anxiety.

Figure 3 shows a funnel plot for evaluating publication bias. The plot is symmetrical, implying no publication bias in the seven studies selected for this meta-analysis.

### Discussion

To our knowledge, this meta-analysis is the first to examine methodological quality and the effects of music intervention on anxiety for patients requiring chronic HD. Although this systematic review included a small number of studies ($n = 7$), we nonetheless found trends in music interventional studies for patients receiving in-center HD. A fair number of music interventional studies have reported benefits to music intervention, such as reducing depression and
anxiety, and increasing quality of life in patients with ESRD. This meta-analysis also clarified the positive effects of music intervention in decreasing anxiety in patients on maintenance HD.

The selected studies used Spielberger’s STAI to measure anxiety and reported the Cronbach’s alpha values were 0.80 to 0.93. A study was excluded during the process of selecting articles for this study because it used a different instrument called Volicer & Bohannon’s Anxiety Questionnaire (Bae, 2009). Considering the number of participants – 175 and 176 patients participated in the intervention and control groups, respectively – an average of 25 persons (range: 15 to 50) participated in each study group, but none of the studies reported sample sizes based on an appropriate power calculation.

Six of the seven selected studies (85.7%) reported that music intervention has significant effects on reducing anxiety, while one study (Choi, 1996) reported that music intervention has significant effects on reducing anxiety, while one study (Choi, 1996)
showed no effects. Choi (1996) explained that the possible reasons could be 1) the pre-mean anxiety score was not high enough in the treatment group (treatment group’s pre-mean anxiety score, 47.13 ± 11.16, and post-mean anxiety score, 43.00 ± 6.36 vs. control group’s pre-mean anxiety score, 47.76 ± 10.56, and post-mean anxiety score, 47.52 ± 12.39; z = 0.09); and 2) the small sample size (treatment group, n = 15 vs. control group, n = 17). Yet the study did not report what a proper sample size would be for the intervention.

The frequency and interval of music provided to the participants varied in the selected studies. Listening durations ranged from 30 to 180 minutes, and frequencies ranged from 3 to 12 times. In a study conducted by Cantekin and Tan (2013), participants listened to pre-recorded music for 30 minutes three times, but despite the short music intervention duration compared to the other selected studies, they reported significa-

Notes: QATQS = Quality Assessment Tool for Quantitative Studies.
siantly reduced anxiety. Similarly, an integrative review on music intervention for pre-operative anxiety pointed out the variability in the duration of the music intervention; a minimum of 15 to 20 minutes (once) of music intervention appears to reduce pre-operative anxiety (Pittman & Kridli, 2011).

Chan and colleagues (2011) also reported music interventions that were diverse in duration or frequency in their systematic review evaluating the effectiveness of listening to music in reducing depressive symptoms in adults. It seems there is a lack of clear standards or guidelines for music interventions. Hence, more studies are required to ascertain the most appropriate music treatment modalities to reduce anxiety in patients on maintenance HD.

To avoid contamination or compensatory rivalry (threats to internal validity) in the selected studies, three studies assigned treatment groups and control groups to a different hospital and the other three studies to different HD schedules (e.g., Monday, Wednesday, and Friday vs. Tuesday, Thursday, and Saturday). One study did not report on how to avoid the possibility of the treatment and control groups co-mingling and possibly affecting study outcomes.

Considering regional distribution, five studies were conducted in Korea, one in Greece, and one in Turkey. More studies written in Korean were included. The reason might be that five extra Korean databases were used to search for relevant studies, and a few unpublished studies, such as master’s or doctoral theses, were included.

In the methodological study quality assessment, controlling confounders and blinding methods were found to be poor. None of the studies included studies in the review were

Heterogeneity: Chi² = 4.43, df = 6 (p = 0.62); I² = 0%.

Test for overall effect: Z = 6.87 (p < 0.00001).
rated “strong” for confounders, which evaluates the percentage of relevant confounders controlled for. Although the studies included pre-tested whether there were significant differences in sociodemographic characteristics between the intervention and control groups, future studies should analyze the effects of music interventions on anxiety according to various personal factors, such as age, gender, educational background, HD vintages, emotional status, music preference, and previous music experiences, or they should rigorously control possible confounding factors since they influence the participants’ responses to music (Bradt, Dileo, & Shim, 2013; Landreneau, Lee, & Landreneau, 2010; Pelletier, 2004). Further, medications such as anxiolytics can influence the effects of music interventions and be confounders in music interventions (Bradt et al., 2013). However, none of the studies included in the review described inclusion or exclusion of patients who took anxiolytics before or during HD. Other factors, such as noise or alarm sounds from machines, may influence music effects, but no study reported on this factor. These factors should also be analyzed and/or controlled in future studies.

Another poorly rated component in the study quality assessment (7 out of 7, “weak”) was blinding. As Bradt and colleagues (2013) pointed out, because of the nature of music interventions, it might be difficult or impossible for the outcome assessors not to be aware of the intervention or exposure status of participants, or for the participants not to be aware of the research questions or purposes.

Our study search initially yielded 387 articles from 10 electronic databases; 7 studies were included in the meta-analysis based on the study selection criteria. Considering the number of advantages associated with music intervention and no restrictions with times of publication, there were relatively few music interventional studies on anxiety in patients on maintenance HD. The reason may stem from the report by Cukor and colleagues (2008) that anxiety is often not perceived as a discrete condition, and consequently, has been relatively understudied in patients with ESRD.

As secondary outcomes of music interventions, physiological responses to music interventions (e.g., pain level perception, immune function, or blood pressure) were also evaluated in addition to psychological responses. Physical responses combined with the psychological effectiveness of music during HD warrants additional investigation.

All studies included in the review used pre-recorded music, not live music. In addition, there was no mention of using a music therapist for the interventions. Future research exploring differences in the effectiveness of using live music vs. pre-recorded music (Nightingale, Rodriguez, & Carnaby, 2013), or music therapists vs. clinicians, such as dialysis nurses (Kim, 2002), may provide valuable information to researchers and clinicians who plan to conduct music interventions in HD centers.

Two potential limitations should be considered when interpreting or generalizing the results from this study. First, there are possibilities of publication bias related to studies with non-significant findings not being published. Second, more articles written in Korean were included in the study, which might provide bias toward the results of this review.

Conclusions and Implications

This integrative review and meta-analysis identified a positive effect of music interventions on reducing anxiety among patients on maintenance HD, implying that patients’ music listening can relieve feelings of anxiety. The music interventions used in the selected studies varied in terms of treatment frequency, dose, and interval. The methodological quality of research also varied. Prior to further systematic evaluation, more numbers of well-controlled clinical studies to reduce anxiety in patients on maintenance HD are warranted so that appropriate music interventional modalities can be ensured for the patients and clinicians in this area.
