Inhibitory interneurons regulate the responses of cortical circuits. In auditory cortical areas, inhibition from these neurons narrows spectral tuning and shapes response dynamics. Acute disruptions of inhibition expand spectral receptive fields. However, the effects of long-term perturbations of inhibitory circuitry on auditory cortical responses are unknown. We ablated ∼30% of dendrite-targeting cortical inhibitory interneurons after the critical period by studying mice with a conditional deletion of Dlx1. Following the loss of interneurons, baseline firing rates rose and tone-evoked responses became less sparse in auditory cortex. However, contrary to acute blockades of inhibition, the sizes of spectral receptive fields were reduced, demonstrating both higher thresholds and narrower bandwidths. Furthermore, long-latency responses at the edge of the receptive field were absent. On the basis of changes in response dynamics, the mechanism for the reduction in receptive field size appears to be a compensatory loss of cortically (CC) driven responses. Our findings suggest chronic conditions that feature changes in inhibitory circuitry are not likely to be well modeled by acute network manipulations, and compensation may be a critical component of chronic neuronal conditions.

Processing of auditory information in the auditory cortex underlies the conscious perception of sound and speech comprehension. Inhibitory interneurons, representing ∼20% of cortical neurons (1), regulate this processing by shaping the spectral tuning (2–13), temporal tuning (14–16), and response dynamics of local excitatory neurons (5–11). Inhibitory interneurons form multiple subtypes on the basis of morphology, physiology, and biochemistry (1, 17) that likely serve distinct roles in cortical processing.

Loss of inhibitory interneurons is observed in conditions that affect cortical processing in humans, and in animal models of human disorders, including aging (18, 19), autism (20), schizophrenia (21–23), traumatic brain injury (TBI) (24), hearing loss (25–28), and tinnitus (29). Often, a particular disease is associated with a specific deficit in a subset of interneurons. For example, rodent models of autism demonstrate a loss of parvalbumin positive (PV+) interneurons (20), whereas aging and TBI models show a greater loss of somatostatin (SST) interneurons than other interneuron populations (19, 24). The disruption of specific interneuron populations may underlie the particular cognitive defects associated with each condition. Therefore, it is necessary to understand the effects following chronic reductions of particular interneuron subtypes.

One mouse model of an adult-onset loss of dendrite-targeting interneurons (DTIs) is the Dlx1 mutant (30). Dlx1 encodes a homeobox transcription factor from the Dlx family that regulates the development, migration, and survival of cortical interneurons (30–32). In Dlx1 mutants, the other Dlx family members compensate for the deficiency and thereby allow interneurons to migrate into cortex (30). At postnatal day 20 (p20) there is no observed loss of interneurons in Dlx1 mutants; however by p30, ∼30% of SST+, neuropeptide Y (NPY+), and calciretin positive (CR+) DTIs undergo apoptosis, whereas soma-targeting, PV+ interneurons are unaffected (30). Following the loss of interneurons, the rate and size of spontaneous and miniature inhibitory postsynaptic potentials are reduced (30). Despite the normally broad expression of Dlx1 in interneurons, there is no change in the intrinsic properties of the surviving interneurons after p30 (33). This partial loss of interneurons is similar to human adult-onset conditions that feature a selective loss of DTIs, such as aging and TBI, because the critical period for spectral tuning in auditory cortex ends before p20 in mice (34). Dlx1 mutants are known to develop seizures, behavioral deficits, and abnormal visual cortical responses (35–37); however, changes in auditory processing are unknown.

Previous attempts to study the deficits in auditory cortical processing in a constitutive Dlx1 knockout (Dlx1−/−) were not successful because Dlx1 also regulates the development of the middle ear ossicles (38, 39). The middle ear bones fuse in the absence of Dlx1 and create a conductive hearing loss that raises auditory brainstem response (ABR) thresholds in Dlx1−/− mice by ∼30 dB, precluding a meaningful study of auditory cortical changes (38, 39). To circumvent this issue, we developed a conditional deletion of Dlx1 restricted to forebrain GABAergic neurons using a floxed conditional allele of Dlx1 and Dlx12b-Cre (H2b-Cre). Dlx12b is an enhancer element of Dlx1 (40, 41). By placing Cre-recombinase under the control of this enhancer, which is not expressed in the primordia of the middle ear, recombination occurs in 95% of cortical interneurons (41). We will refer to these Dlx1−/−;H2b-Cre animals as conditional knockout animals (cKO) and heterozygous littermates (Dlx1+/−;H2b-Cre) as controls (CT).

Results

Dlx1−/−;H2b-Cre Mice Lack a Subset of Dendrite-Targeting Interneurons. We validated the conditional deletion of Dlx1 by confirming that the loss of dendrite-targeting interneurons (DTIs) in Dlx1−/−;H2b-Cre (cKO) animals was consistent with the constitutive null mutants, Dlx1−/−. As in Dlx1−/− mutants, ∼30% of dendrite-targeting, SST+, NPY+, and CR+ interneurons were lost by p45 in cKO mice, whereas no change in the number of soma-targeting, PV+ interneurons was observed (means ± SD labeled cells/mm²: SST, CT 16.2 ± 1.0 and cKO, 10.4 ± 1.6, P < 0.05; NPY, CT 49.5 ± 2.5 and cKO 32.2 ± 3.4, P < 0.05; CR, CT 55.2 ± 1.5 and cKO 44.8 ± 3.0, P < 0.05; PV, CT 134.6 ± 5.6 and cKO 139.5 ± 5.6, P >

and Dlx1<sup>−/−</sup>/I12b-Cre mice, the conditional knockout successfully avoided the elevated peripheral auditory thresholds of Dlx1<sup>−/−</sup> mice (38). The cKO mice, in contrast to Dlx1<sup>−/−</sup> mice, had normal ABR thresholds (medians: CT = 30 dB, cKO = 25 dB, P = 0.17, n = 4 and 3; Fig. 1A and B). In sum, cKO mutants have the same selective loss of DTIs as the constitutive Dlk1 mutant and develop a neurological condition independent of peripheral changes in the middle ear. Therefore, we used Dlk1 cKO mutants to characterize changes in auditory cortex function that arise following the loss of DTIs.

**Dlx1<sup>−/−</sup>/I12b-Cre Cortical Units Have Restricted Receptive Fields.** We determined the effect of the loss of DTIs on auditory processing by recording responses to pure tones and constructing frequency response areas (FRAs, firing rate as a function of tonal frequency and intensity, Fig. 2A–D). We recorded from single-units in auditory cortical core areas, the primary auditory field (A1) and the anterior auditory field (AAF), across all cortical layers of cKO mutants (n = 58 units, eight animals) and controls (n = 54 units, eight animals) and quantified the size of the response area (area of FRA above 1/4 peak value), response threshold (lowest intensity in the response area), and spectral bandwidth (number of octaves responding at an intensity above threshold). In cKO cortical units, response area sizes were reduced (medians: CT = 177 dB*octaves, cKO = 144.5 dB*octaves, P < 0.005, Fig. 2E and Fig. S2D). This was a combined effect of higher thresholds (medians: CT = 20 dB, cKO = 25 dB, P < 0.001, Fig. 2C and F and Fig. S2E) and narrower bandwidths (bandwidth at 20 dB above threshold: medians: CT = 1.1 octaves, cKO = 1.0 octave, uncorrected P < 0.05, Fig. 2D and G, Fig. S2F; see SI Results for details of ANOVA). Contrary to the effects of acute, pharmacological blockades of inhibition, which broaden spectral tuning (6–12), the chronic loss of DTIs led to narrower spectral tuning, which is a reduction in receptive field size.

To test whether these changes emerge in cortex or are already present subcortically, we recorded single units across multiple divisions in the auditory thalamus (CT: 31 units from two animals; cKO, 65 units from three animals). In contrast to cortical FRAs, cKO and control thalamic FRA response areas were not significantly different (medians: CT = 109 dB*octaves, cKO = 142 dB*octaves, P = 0.06, Fig. 2H and Fig. S3; see SI Results for further characterization). Thus, the changes observed in cortex were not present in the thalamus—the preceding subcortical station—and likely arise in cortex.

**Fig. 1.** Dendrite-targeting interneurons are reduced in cKO mutants. (A) Sections of auditory cortex from control and cKO mice labeled for various interneuron markers (from left to right, top to bottom: parvalbumin, somatostatin, neuropeptide Y, calretinin, vasoactive intestinal peptide). (B) Cell count in control and cKO mice: PV<sup>+</sup> (P > 0.05, n = 3 animals), SOM<sup>+</sup>, NPY<sup>+</sup>, CR<sup>+</sup>, and VIP<sup>+</sup> interneurons (P < 0.05, n = 3 animals for each).

**Fig. 2.** Cortical spectral tuning area is reduced in cKO mutants. (A and B) the population mean FRAs aligned by CF for auditory cortical units. (C) Difference, cKO – control. (D) Difference with units aligned by threshold. (E–G) Size of responsive area of cortical units (P < 0.01, P < 0.001, and P < 0.05; n = 54 CT and 58 cKO). (H) Size of responsive area of thalamic units (P > 0.05; n = 30 CT and 61 cKO).
processes and horizontal cortical spread of activity (44, 45). Therefore, we measured the response dynamics at the center and edge of the FRA to explore how effectively CC connections drive activity in cKO mutants.

To quantify the response dynamics, we used peristimulus time histograms (PSTHs, Fig. 3A–C) for two different intensity regions near the characteristic frequency (CF ≥ 0.2 octaves when the description of CF was moved forward, this became redundant). To study the combined effect of TC and CC connections, the first PSTH was from stimuli in the center of the FRA at high intensities (60–80 dB, Fig. 3E). To focus on primarily CC-driven activity, the second PSTH was from the edge of the FRA at low intensities (threshold ± 10 dB, Fig. 3F). As with acute blockades of inhibition (6–12), baseline firing rates were higher in cKO units during the 50 ms preceding stimulus presentation and before driven responses began (medians: CT, 1.11 Hz and cKO, 2.38 Hz, P < 0.005, Fig. 3D). Beyond the change in baseline firing, there were no significant differences between cKO and control PSTHs at high intensities where both TC and CC inputs contribute (significance judged as at least five consecutive rank sum P < 0.05, in which case all consecutive, significant points are reported; values 0–9 ms (before the response onset of most units) pass this criterion, Fig. 3E). In contrast, at low intensities where CC connections dominate, cKO responses begin earlier but are overtaken by control responses (cKO > CT, 0–16 ms; CT > cKO, 25–34 ms; at least five consecutive rank sum P < 0.05). In cKO mutants, responses driven by TC and CC connections appear to be normal in timing and rate, but baseline firing rates are higher and responses driven primarily by CC connections are abnormal in timing, magnitude, or both. We therefore quantified the response timing and response magnitude in greater detail.

**Dlx1<sup>−/−</sup>12b-Cre Cortical Units Lack Long-Latency Responses.** To investigate the differences in temporal response dynamics for individual units, we quantified the response onset latency (time to half the peak height from baseline). The response latency of control units is longer at low intensities near threshold compared with high intensities (medians: CT-high = 15.5 ms, CT-low = 22 ms, Bonferroni corrected P < 0.001, Fig. 3G) in agreement with previous results where CC driven responses have longer latencies (44, 45). However, in cKO units, the response latency at low intensities occurs significantly earlier than in control units (medians: CT-low = 22 ms, cKO-low = 16 ms, Bonferroni corrected P < 0.05, Fig. 3G). Interestingly, Control latencies at high intensities were not significantly different from either high or low intensity latencies for cKO units (medians: CT-high = 15.5 ms, cKO-high = 12 ms, Bonferroni corrected P > 0.05; medians: CT-high = 15.5 ms, cKO-L = 16 ms, uncorrected P = 0.31, Fig. 3G). In other words, the response timing in cKO units at both high and low intensities was similar to central regions predominantly driven by TC connections in controls, and neither was similar to the primarily CC driven edge responses of controls. The response latencies for cKO units at low intensities were longer than at high intensities (medians: cKO-high = 12, cKO-low = 16 ms, Bonferroni corrected P < 0.05, Fig. 3G) presumably because the response latencies of subcortical stations are also stimulus intensity dependent (46). Therefore, receptive fields did not simply change shape, but the long-latency responses at low intensities normally driven by CC connections appeared to be absent in the cKO population.

To extend analysis of changes in response timing to the entire FRA, we calculated two short-time FRAs on the basis of 10-ms windows centered either on the response onset or response termination (termination: time at half the peak value after the peak response, Fig. 4A–C). It has previously been shown (45) that the central, TC-driven FRA region becomes active first (Fig. 4D) and gives way to activity at the CC-driven edges of the FRA (Fig. 4B). Therefore, the FRA shapes from the response onset were negatively correlated. This correlation was observed for control units (median: +0.05, signed rank P < 0.05, Fig. 4D), suggesting that inputs at the edges of the FRA dominate the late portion of the response. In contrast, the onset and termination responses of cKO units were positively correlated (median: +0.05, signed rank P < 0.05, Fig. 4D), indicating that the same FRA regions tend to be active throughout the response. The correlations for the two groups are significantly different (medians: CT = +0.05, cKO = +0.05, rank sum P < 0.01, Fig. 4D). Therefore, cKO units do not appear to develop responses at the edge of the FRA over time as control units do. Combined with the decrease in response area and lack of long-latency responses, this result reinforces the idea that only central, TC-driven responses remain in the FRAs of cKO units.

**Dlx1<sup>−/−</sup>12b-Cre Cortical Responses Are Less Sparse.** To explore changes in firing rate, we determined the response rate as a function of stimulus intensity for tones near CF (±0.2 octaves when the description of CF was moved forward, this became redundant). To in-
After the loss of DTIs, we found that receptive fields for cortical multiunits for 80-dB stimuli were less sparse following the loss of inhibition by decreasing the effectiveness of inputs, such as a decrease in the input resistance of excitatory neurons, and compensatory changes in inhibitory postsynaptic potentials (IPSPs) (33). This result has two implications for the current work. First, the amplitude of excitatory connections onto inhibitory interneurons decreases, and the rate of excitatory synaptic activity and intrinsic properties of excitatory neurons, and compensatory changes in inhibitory neurons may identify differences in Dlx1 mutants; however, the difference observed in cKO mutants. Another possibility is that the intrinsic properties of excitatory neurons could change to reduce the expected outcome would be the reduction in CC-driven responses. This cortical receptive field phenotype is in agreement with observations from the visual system of Dlx1−/− mice where the range of stimuli that drive responses is also reduced in most V1 cortical neurons and thalamic cortex. Therefore, responses were less sparse following the loss of DTIs.

The decrease in sparseness, abnormal EEG activity, and increase in baseline firing rate are the only data in agreement with pharmacological blockades of inhibition (6–12). Previous studies demonstrated that acute reductions of inhibition expand the breadth of receptive fields and lengthen cortical responses (6–12). We observed the opposite following the chronic decrease in inhibition and identified a selective decrease in responses at the edges of the receptive field. As overactivity is still present, it suggests that compensation occurs at the FRA edges to weaken and limit the spread of overactivity.

**Discussion**

We used Dlx1−/−;112b-Cre mutants (cKO) to study the effects of a partial loss of DTIs on auditory cortical processing. These animals have normal peripheral hearing but an ∼30% reduction in SOM+, NPY+, CR+, and VIP+ interneurons that develops after the end of the critical period in auditory cortex (Fig. 1). As SST and VIP are believed to be mutually exclusive interneuron makers in mouse cortex (1, 17) and derive from the medial and caudal ganglionic eminence progenitor populations, respectively (47–52), this demonstrates that interneurons from distinct progenitor pools are affected by the Dlx1 mutation.

**Loss of Functional Cortical–Cortical Connectivity in Dlx1−/−;112b-Cre Mice.** After the loss of DTIs, we found that receptive field sizes were reduced in single units from core areas of auditory cortex in cKO mutants due to higher thresholds and narrower bandwidths (Fig. 2). We obtained evidence that this reduction does not occur in the thalamus and therefore emerges in cortex (Fig. S3). As descending cortical fibers can modulate subcortical function, it is possible that a more detailed investigation of subcortical activity may appear to result directly from changes in thalamic processing. This cortical receptive field phenotype is in agreement with observations from the visual system of Dlx1−/− mice where the range of stimuli that drive responses is also reduced in most V1 cortical neurons and thalamic circuitry remains intact (36). This commonality suggests that the reduction in cortical receptive field size may be a general response to the loss of dendrite-targeting inhibition. In auditory cortex of cKO mice, the edges of the FRAs, which normally have long-latency responses, were absent (Figs. 2–4). Instead, the edges of cKO FRAs have response latencies comparable to short-latency, central responses of control units (Fig. 3). Furthermore, Control responses progress from the center to the edge in a patterned fashion; however, in cKO responses the central region is active at both the response onset and termination as if the longer-latency edge responses were absent (Fig. 4).

The absent FRA edges are usually driven primarily by CC connections to drive responses. There are several possible mechanisms for this change, including decreased CC synaptic strength, different cell intrinsic properties of excitatory neurons, and compensatory changes in inhibitory circuitry. Weakened excitatory inputs have been observed in the hippocampus of Dlx1−/− mutants (33). The amplitude of inputs from excitatory neurons onto inhibitory interneurons decreases, and the rate of excitatory synaptic activity and intrinsic properties of the surviving interneurons were not affected by the loss of Dlx1 (33). This result has two implications for the current work. First, the intrinsic electrical properties of the surviving interneuron populations appear to be unaffected by the loss of Dlx1. Second, Dlx1 mutants compensate for the loss of inhibition by decreasing excitatory drive. If the amplitude of excitatory connections onto excitatory neurons in auditory cortex decreases in this manner, the expected outcome would be the reduction in CC-driven responses that we observed in cKO mutants. Another possibility is that the intrinsic properties of excitatory neurons could change to reduce the effectiveness of inputs, such as a decrease in the input resistance of dendrites. Alternatively, the remaining inhibitory
interneurons could increase the strength of their responses and overcompensate for the loss of DTIs, thereby suppressing normal CC activity. Computational modeling in V1 of Dlx1 mutants suggests this alternative (56). Regardless of the mechanism, the observed changes in cortical receptive fields will limit the complexity of network processing.

The reduction in edge responses may reflect compensation to reduce overactivity observed in eKO mice (Fig. 5 and Fig. S1). Whereas the number of single-unit spikes remained constant in auditory cortex in response to tones, the number of multiunit spikes increased by 50%, indicating that overactivity to normal stimuli develops following the loss of DTIs and responses become less sparse. Combined with the increase in baseline firing rates and seizure-like activity, these are the only results in agreement with acute, pharmacological disruptions of inhibition. Pharmacological blockades of inhibition have been shown to broaden spectral tuning, including lowering thresholds and revealing longer latency responses (6–12). However, the opposite results were observed in our study following the chronic disruption of dendrite-targeting inhibition and are likely to reflect compensation. Therefore, approaches that examine only the acute effects of reducing interneuron function are likely to be incomplete models of chronic human neurological conditions but remain valuable for determining the functional role of these circuit elements. If compensation in Dlx1 mutants works to oppose acute changes, one could predict that acute inhibition in Dlx1 mutants will enhance the spectral edges of the receptive field driven by CC connections. The opposite, acute activation, would then be predicted to selectively suppress the spectral edges of the receptive field. Further studies are needed to test these hypotheses.

Role of Dendrite-Targeting Interneurons in Health and Disease. Reduction of inhibition is a component of many neurological conditions, including hearing loss, aging, TBI, and neuropsychiatric diseases (19–29). Following hearing loss, cortical response thresholds are higher at the affected frequencies and a subsequent loss of inhibition follows (25). This weakened inhibition has been linked with the perception of tinnitus (29). Tinnitus may develop as excitation and inhibition find a new balance following the reduction of inhibition. Dendrite-targeting interneurons are also lost selectively after TBI (24). Both TBI and Dlx1 mutant mice display an increased susceptibility to seizures (24, 30). The cognitive symptoms in TBI patients may also be driven by the loss of DTIs. DTIs are also lost during aging, which may lead to progressive deficits in speech comprehension (19). Responsiveness to one component of speech, FM sweeps, relies on asymmetric CC connectivity and the response dynamics of both excitatory and inhibitory interneurons (14, 18, 53–55). The aging-induced loss of interneurons followed by a compensatory loss of excitatory CC inputs may contribute to deficits in speech comprehension. Compensatory mechanisms may account for many symptoms of complex neurological conditions.

The described long-term changes may reveal some of the normal function of DTIs. As DTIs are recruited by CC activity, they are well suited to mitigate overactivity (56). Also, DTIs target dendrites, where excitatory CC connections dominate (57–64) and respond to stimuli with similar timing as excitatory cortical neurons (65). Under healthy conditions, activity propagated by CC connectivity will elicit a sufficient inhibitory response to shape cortical responses and maintain a safe balance of excitation and inhibition. After the loss of DTIs, excitatory CC connections will be uninhibited but may subsequently weaken to normalize the overall level of excitation. This compensation would replicate a state of tonic DTI inhibition. Fitting with this hypothesis, responses normally driven by CC connections are lost in eKO mutants but signs of overactivity remain. When faced with overactivity, the nervous system may sacrifice connectivity and computational power for stability. Deficits in neurological conditions with reduced inhibition may reflect compensatory changes as well as the direct effects of interneuron losses. It is therefore necessary to study long-term compensatory mechanisms following the loss of specific interneuron populations to better understand human neurological conditions.

Methods

Experiments were performed on Dlx1−/−I12b-Cre and Dlx2−/−I12b-Cre mice using procedures approved by the University of California San Francisco Institutional Animal Care and Use Committee and in accordance with National Institutes of Health guidelines. For details of the generation of these mice and histological verification see SI Methods.

Electrophysiology. EEG observations were made by using a time-locked video EEG monitoring system (Pinnacle Technology). For EEG recordings, mice were surgically implanted in the left and right frontal and parietal cortices with electrodes. Each mouse was anesthetized with isoflurane at an areflexive state. Head mounts were attached with conductive stainless steel screws to act as recording electrodes. Dental cement was used to secure the head mount, and animals were allowed to recover for 3–5 d before recording sessions were initiated. Differential EEGs were collected from 2-mo-old animals over 8-h recording sessions.

Auditory brainstem responses were assessed under ketamine and xylazine anesthesia. Silver wires were inserted through the skin on either side of the brainstem and the forehead. Event-related potential evoked by clicks at various intensities were recorded (TDT Sys3 with BioSigRP; Tucker Davis Technologies). To collect extracellular recordings, male and female animals aged between 3–5 wk of age were anesthetized with isoflurane with a mixture of ketamine and xylazine. A small craniotomy was then performed over auditory cortex. Primary auditory cortical areas were identified by a multiunit response latency of ~10 ms (TDT Sys3 with Brainware; Tucker Davis Technologies). A frequency gradient reversal between A1 and AAF was not consistently observed in all control and mutant mice; therefore, a sampling was taken from midlow frequencies and short latency (~15 ms) areas. Auditory thalamus was identified as the auditory responsive region with latencies around 8 ms near the stereotactic coordinates 3.2 mm posterior, 1.9 mm lateral, and 3.0 mm ventral of Bregma. Extracellular recording traces were collected with 16-channel probes (NeuroNexus) on a 32-channel recording system (Neuralynx). Threshold crossings at 4 SD were collected as multiunit spikes and these were sorted offline using KlustaKwik (written by Ken Harris) followed by manual supervision to identify single-unit responses. Only single units and multiunit sites that contained more than 500 events and doubled their average firing rate in response to tones were analyzed.

Stimuli and Analysis. Tones spanning 4 octaves (4–32 kHz, 0.1 octave spacing) and 70 dB (10–80 dB, 5-dB spacing) lasting 50 ms were presented every 750 ms. In some experiments, tones were followed 70 ms later by a short burst of white noise to focus on tone onsets. No significant differences in tone responses for the two conditions were observed and the data were pooled. However, we limited all analysis to action potentials that occurred less than 70 ms after tone onset. The FRA was determined as the areas above 1/4 peak response after subtracting the baseline. Threshold was determined as the lowest intensity bin in the FRA, and CF was the middle frequency bin at that intensity. Multiple intensity regions were selected over multiple spectral regions for the PSTH because the spectral edges of the tuning curve were sometimes at the edge of the frequency sampling space we tested and could not always be reconstructed with confidence. Response onset was estimated as the time to reach 1/2 of the peak response of the PSTH at that intensity. Response termination was the time point to fall to 1/2 of the peak value after the peak of the PSTH. When correlating the onset FRA and the termination FRA, 10-ms windows centered on both times were used and the original FRA was applied as a mask before the correlation was calculated. Data analysis was performed in Matlab (MathWorks) using custom software. Unless otherwise noted, all statistical tests are nonparametric, Wilcoxon rank-sum tests. Therefore, data median data values are given in the text rather than means. However, for the purpose of display, the data are plotted as mean ± SEM. All units were used in each analysis (eKO: 58 cortical, 65 thalamic; CT: 54 cortical, 31 thalamic).
