I. Introduction

Laser-driven rf electron guns\(^1\) are potential sources of high-current, low-emittance, short bunch-length electron beams, which are required for many advanced accelerator applications, such as free-electron lasers and injectors for high-energy machines. In such guns the design of which was pioneered at Los Alamos National Laboratory\(^2\) and which is currently being developed at several other laboratories, a high-power laser beam illuminates a photo-cathode surface placed on an end wall of an rf cavity. The main advantages of this type of gun are that the time structure of the electron beam is controlled by the laser, eliminating the need for bunchers, and that the electric field in rf cavities can be made very strong, so that the effects due to space-charge repulsion can be minimized. In this paper, we present an approximate but simple analysis for the transverse and longitudinal emittances in rf guns that takes into account both the time variation of the rf field and the space-charge effect. The results are compared and found to agree well with those from simulation. In the following, we review the theory\(^3\) in Sections II and III, and the simulation results\(^4\) in Section IV.

II. Analysis of RF Effects\(^5\)

The structure of a rf gun cavity is schematically illustrated in Fig. 1. The cavity consists of \((1/2+n)\)-cells, the first cell being a half-cell so that electrons see the maximum accelerating field as they are emitted from the cathode. The accelerating field in the cavity will be assumed to be of the following simple form:

\[
E_z = E(z) \cos k z \sin (\omega t + \phi_0); \quad E(z) = E_0 \delta(z_0 - z).
\]

Here \(\lambda\) is the rf wavelength, \(k = 2\pi/\lambda\), \(c\) is the velocity of light, \(\omega = kc\), \(\phi_0\) is the rf phase as the electron leaves the cathode (located at \(z = 0\)) at \(t = 0\), \(E_0\) is the peak accelerating field, \(\theta\) is the step function, and \(z_0 = (n + 1/2)\lambda/2\) is the location of the cavity exit. When \(E_z\) is independent of transverse coordinates, the transverse fields are linear in transverse coordinates and are given by

\[
E_x = -\frac{r}{2} \frac{\partial}{\partial z} E_z, \quad \Delta_E = \frac{r}{2c} \frac{\partial}{\partial \theta} E_z.
\]

Here \(r\) and \(\theta\) are the cylindrical coordinates. The fields, Eq. (1) and Eq. (2), can be considered as a \(\pi\)-mode excitation of an ideal cavity.\(^2\)

The equations for rf acceleration for \(z < z_0\) are

\[
\frac{dy}{dz} = \frac{eE_0}{2mc^2} (\sin(\phi) + \sin(\phi + 2kz)).
\]

The force in the radial direction is given by \(F_r = e(E_z - \beta c B)\), which, using Eqs. (1) and (2), can be written in the following form:

\[
F_r = e\left\{-\frac{1}{2c} \frac{d}{dt} \left[E(z) \sin k z \cos (\omega t + \phi_0)\right] - \frac{1}{2} \left[\frac{d}{dz} E(z)\right] \sin \phi + \frac{(\beta - 1)}{2} \left[\frac{d}{dz} E(z)\right] \sin k z \cos (\omega t + \phi_0)\right\}.
\]

The transverse momentum is obtained by integrating Eq. (9) with respect to time \(t\). We assume that the transverse deflection is small so that the radius \(r\) can be regarded as constant. The first term in the above is a total derivative of an expression that vanishes at the cathode surface and outside the cavity, thus its contribution to the transverse momentum vanishes. The contribution from the third term is small because of the \((\beta - 1)\)-factor. Thus the main contribution comes from the second term, which is important only in the region where \(dE(z)/dz\) is non-vanishing, i.e., near the cavity exit. With \(E(z)\) given by the step function (see Eq. (1)), the dimensionless transverse momentum at the cavity exit in the Cartesian coordinate, \(p_x = \beta p_x^*\), where \(x^*\) is the angle in the \(x\)-direction, becomes

\[
p_x = (\alpha k \sin \phi_0)x.
\]

Equations (8) and (10) are the basis for our discussion of the rf-induced emittances. The phase \(\phi_t\) varies over the length of the electron bunch, \(\phi_t = (\phi_0 + \Delta \phi) - k \Delta z\), where \(\Delta \phi\) is the average phase. Thus the transverse phase-space distribution consists of a collection of lines with different slopes corresponding to different \(\Delta \phi\), as illustrated in Fig. 2. The normalized transverse emittance is defined\(^2\)

\[
e_x = \sqrt{\left\langle p_x^2 \right\rangle - \left\langle p_x \right\rangle^2},
\]

where the angular brackets refer to the average values. Assuming that the electrons' density distribution is Gaussian, with rms transverse and longitudinal lengths given respectively by \(\sigma_x\) and \(\sigma_L\), we find from Eqs. (9) and (11) that the emittance is at a minimum for \(\phi_t = \pi/2\) and

\[
e_x^d = \alpha k^2 \sigma_x^2 \langle \cos(\phi_0) \rangle: \langle \phi_0 \rangle = \pi/2.
\]

In the above, the superscript \(\text{rf}\) refers to the fact that we are considering the rf-induced effects.\(^6\)

**Work performed under the auspices of the U.S. Department of Energy by the Lawrence Livermore National Laboratory under Contract No. W-7405-ENG-48.
The longitudinal emittance is defined as 
\[ e_x = \sqrt{\langle (\Delta p_x)^2 \rangle} \langle (\Delta x)^2 \rangle - \langle \Delta p_x \Delta x \rangle \],
(14)
where \( \Delta p_x = \Delta (\beta_x) = \Delta \gamma \) for the relativistic case \( \beta = 1 \). We write \( \gamma = (\gamma_0 + \Delta \gamma) \), and expand Eq. (8) in \( \Delta \beta = -k \Delta x = \gamma - (\Delta \gamma) \). Setting \( \psi = \pi/2 \) to minimize the transverse emittance, we obtain
\[ \Delta \gamma = \alpha k \Delta x = \frac{1}{2} \left[ (\gamma_0 - 1) k^2 (\Delta x)^2 - \frac{\alpha k^3}{3!} (\Delta x)^3 + \cdots \right]. \]
(15)
The nonlinear terms in the above contribute to the longitudinal emittance, and one obtains to the lowest order
\[ e_x^0 \simeq \sqrt{3} (\gamma_0 - 1) k^2 \alpha^2. \]
(16)

III. Analysis of the Space-Charge Effects

A repulsive force attributable to space charge causes the emittance to increase. To study this effect, we assume that all electrons are moving with the same velocity, \( v \), in the \( x \)-direction. In the reference frame moving with the electrons, the electromagnetic interaction is completely described by a purely electrostatic field \( E' \). The field components in the laboratory frame which give rise to the \( x \) and \( z \)-components of the force are given by the Lorentz transformation \( E_x = \gamma E'_x \), \( B_y = \gamma (\beta/c) E'_x \), \( E_z = E'_z \). Here, \( B_y \) is the magnetic field. The components of the force are
\[ F_x = \pm \gamma E'_x, \quad F_z = \pm \delta E'_z. \]
(17)
In the following, we assume the charge distribution to be cylindrically symmetric, so that we do not need to consider \( F_z \) separately. It can be shown that the force given by Eq. (17) vanishes as \( \gamma \to \infty \) for \( \gamma \gg A \), where \( A = \sigma_I/c_0 \) is the aspect ratio. Thus we can write \( F = f(\gamma) \gamma \), where \( f(\gamma) \) is a function slowly varying in \( \gamma \) for \( \gamma \gg A \). The contribution to the dimensionless momentum due to the space-charge force is given by
\[ (p_x, p_y, \Delta p_x) = p = \frac{1}{mc} \int \frac{1}{\gamma} f(\gamma) \, dz. \]
(18)
We evaluate Eq. (18) approximately by noting that the factor \( 1/\sqrt{\gamma} \) in the integrand decreases rapidly as \( \gamma \) becomes large. Thus we replace \( f(\gamma) \) by \( f(1) \) and \( dz \) by Eq. (8). The result is
\[ e_x^{\text{ind}} = \frac{1}{4} \frac{1}{\sin \theta_0} \frac{1}{I_x} \mu(\Lambda); \quad i = x \text{ or } z, \]
(19)
where \( I \) is the peak current, \( I_x = 17,000 \) Amp known as the Alfven current, and the functions \( \mu(A) \) are defined in terms of the normalized field \( \xi = \xi(I) / (c)I \alpha_0 \) by
\[ \mu_x(A) = \sqrt{\xi_x^2 (\Lambda^2) - (\xi_x)^2}, \quad \mu_z(A) = \xi^2 (\Delta^2) - (\xi_z^2 (\Delta^2). \]
(20)
Note that \( \mu(A) \), being dimensionless, are functions of \( A \) only. For the Gaussian charge distribution, these functions are approximately given by
\[ \mu_x(A) = \frac{1}{3 A + 5}, \quad \mu_z(A) = \frac{1.1}{1 + 4.5 A + 2.9 A^2}. \]
(21)

How do the rf-induced and the space-charge induced emittance add? It turns out that there are correlations between those two effects so that the total emittance \( e^t \) is given by
\[ \sqrt{(e_x^0)^2 + (e_x^{\text{ind}})^2} < e_x < e_x^0 + e_x^{\text{ind}}. \]
(22)

A more detailed derivation of the results in Sections II and III, as well as the application of these results to the case where the electron distribution is uniform in a cylinder, can be found in Ref. 5.

IV. Comparison with Simulations

The program PARMELA, modified by McDonald to include the emission of electrons from a photocathode by a laser pulse, has been used to simulate the beam dynamics in the laser-driven rf guns. We have studied a \( (1/2 \times 2) \)-cell, 1269 MHz, \( E_0 = 30 \) MV/m cavity, generating 1 nC, \( \sigma_I = \sigma_I/c_0 = 6 \) ps bunches. The laser spot size is \( \sigma_I = 3 \) mm. These are the parameters for a possible high-brightness gun for an LBL-LLL-SLAC collaboration.

First, the space-charge interaction is turned off in the simulation to study the rf effects alone. In this simulation we use the simple rf field configuration given by Eqs. (1) and (2). In comparing Eq. (7) with simulation, it is found that the exit phase \( \theta_0 \) from theory and from simulation agree within 10% for \( \theta_0 = 0 \). Note that the theory is not expected to be valid for a small value of \( \sin \theta_0 \).

The transverse emittance \( e_x^{\text{ind}} \) versus \( \theta_0 \) (at the center of the electron bunch) is presented in Fig. 3. We see that the optimized emitting phase \( \theta_0 \) from simulation is smaller by \( 7^\circ \) than that predicted by theory (obtained by setting \( \theta_0 = 90^\circ \) in Eq. (7)). If the two curves in Fig. 3 are shifted relative to each other so that their minima coincide, then \( e_x^{\text{ind}} \) from the simulation is about twice as large as that from the theory. The discrepancy seems due to the fact that the bunch radius is assumed to be constant in deriving Eqs. (12) and (13); in simulation, it is found that the bunch radius increases by about a factor of 1.5 as the bunch travels from the cathode to the cavity exit. Note that the emittance given by Eqs. (12) and (13) is proportional to \( \sigma_I^2 \). The \( \sigma_I^2 \)-dependence of the transverse emittance agrees well with simulation results using different values for \( \sigma_I \).

The longitudinal emittance \( e_x^{\text{ind}} \) from simulation agrees with that predicted by theory (Eq. (6)) within a factor of two. When the emitting phase \( \theta_0 \) corresponds to the minimum transverse emittance, \( \theta_0 = 58^\circ \), the agreement is even better. Figure 4 compares \( e_x^{\text{ind}} \) obtained from the simulation with that from the theory for different values of the laser pulse length \( \sigma_I \) for \( \theta_0 = 58^\circ \).

The effects due to the nonlinearity of the rf field in a practical cavity design is checked by comparing the results of PARMELA runs using a linear rf field given by Eqs. (1) and (2), with those using the rf field calculated by SUPERFISH based on a cavity geometry similar to the BNL design. The effect of the nonlinearity on the transverse emittance is found to be small. However, electrons gain more energy in the rf field calculated by SUPERFISH.

The emittance growth due to the space-charge effect is studied by calculating the total emittance \( e_x \) including the space-charge interaction in

Fig. 2. Electron distribution in transverse phase space due to time-dependent focusing of the rf field.
