Title
Do Investors Forecast Fat Firms? Evidence from the Gold Mining Industry

Abstract: Conventional economic theory assumes that firms always minimize costs given the output they produce. News articles and interviews with executives, however, indicate that firms cut costs when they are in economic distress, and grow fat when they are relatively wealthy. We explore this hypothesis by studying how the stock market valuations of gold mining companies vary with gold prices. The value of a cost-minimizing, profit-maximizing firm is convex in the price of a competitively supplied input or output, but we find that the stock values of many gold mining companies are concave in the price of gold. We show that this is consistent with fat accumulation when a firm grows wealthy. We then address a number of potential alternative explanations and discuss where fat in these companies might reside.
I. Introduction

Organizations do not always minimize costs or maximize value. There can be sheer inefficiency or rent dissipation. In this paper we take a simple empirical approach to such “fat” by testing a rather general theoretical property of value maximization. The empirical results suggest that many gold mining companies grow fat when they get rich, and that the amounts concerned may be quite large.

We begin by recalling why simple maximizing theory predicts that a firm’s value should be a convex function of exogenous prices. The result is a simple application of real option theory; it requires no assumptions about functional forms or elasticities of the industry demand function or the firm cost function. We then show that the convexity result can fail if the firm grows “fatter” — i.e., dissipates a larger share of value — as the firm becomes richer.

We apply the theory to the gold mining industry. The industry is particularly attractive for this test because gold prices are quite exogenous to a gold mining firm and cause large changes in the value of the firm. We estimate the relationship between the price of gold and the stock market equity valuation of 17 gold-mining firms. We find that in nearly half these firms, the relationship is significantly concave. We address potential alternative explanations for this surprising finding and argue that they are either unlikely to have a concavifying effect on the estimated relationship or are unlikely to have an effect of the concavity magnitude that we find.

We believe that the approach we present offers a convincing demonstration that fat, in some form, exists and is important. Unfortunately, however, this approach only bounds from below the quantity of fat; it does not permit direct estimation of the quantity. As a result, it does not allow for useful cross-firm comparisons of fat.

In section II, we present the theoretical explanation for why the value of a fat-free firm would be convex in exogenous prices. We then show how fat could disrupt this result, and how concavity of the value function could be used to infer a lower bound on fat. In section III, we apply the theory to empirical analysis of the gold mining industry by
estimating the response of the equity value of gold mining firms to changes in the price of gold. Section IV argues that various other potential explanations seem unlikely to account for the significant concavity that we find. Section V asks where such fat might be. We conclude in section VI.

II. How Firm Value Responds to Price Shocks

A. The Value Response of a Fat-Free Firm

The maximized value of a firm is a (non-strictly) convex function of any exogenously-determined price it faces, holding constant other prices and the constraints and terms of trade facing the firm. This fundamental (and well known) result holds whether the price is that of an input, an output, or a good that is sometimes an input and sometimes an output. The result does not depend on assumptions about production technology (beyond assuming that prices do not affect technological possibilities) or about the shape or elasticity of demand.

To recall why, note that for any fixed production plan, the firm’s value is linear in each price.\footnote{In this paper, we call a function “linear” if it has constant slope; we do not imply that it passes through the origin.} For example, if a gold mining firm ignored changes in the price of gold and just mined a given quantity, say \(x\) ounces, the firm’s value would be \(v(p_g, x) \equiv p_g x - C(x)\), which is linear in the price of gold, \(p_g\). If \(p_g\) were to change from $300 to $400 per ounce, \(v(p_g, x)\) would rise by $100\(x\), which is exactly as much as it would rise if \(p_g\) went from $400 to $500 per ounce. Thus, given a production plan with output \(x\), the firm’s value \(v(p_g, x)\) would be linear in the gold price \(p_g\).\footnote{A similarly linear relationship would hold if it were an input such as labor, rather than the firm’s output, whose price was changing while the firm kept the same production plan. The slope would be \(-L\), where \(L\) is that production plan’s labor input, rather than \(+x\); but, as before, the slope would not change with the price.}

However, the firm can switch among production plans, and typically will do so in maximizing value. Gold mining firms expand output when the price of gold increases and
reduce output when gold prices fall: Moel and Tufano (2002) find that firms often close and reopen gold mines in response to changes in gold prices, consistent with real-option analysis. Since the firm can profitably change production plans, its maximized value, as a function of price, is an upper envelope of straight lines, \( V(p_g) \equiv \max_x v(p_g, x) \), and hence is convex. This well-understood fact is illustrated in figure 1.

As the argument suggests, by the envelope theorem \( V'(p) = x(p) \), so the slope of the value function should be equal to the firm’s anticipated output quantity \( x \), or, in the long-run valuation of a gold mining firm, something like the firm’s economic reserves.\(^3\) More interestingly, the convexity of \( V \) is closely related to the “real option” value to the firm of being able to adjust quantities in response to price changes. Since \( V'(p) = x(p) \), it follows that \( V''(p) = x'(p) \), so a natural measure of the curvature of the \( V \) function, \( pV''(p)/V'(p) \), the elasticity of the slope of \( V \) with respect to price, is equal to the elasticity of the firm’s supply with respect to price, \( px'(p)/x(p) \).

While this proof of convexity of the firm’s value function is straightforward when only one price varies, other prices facing the firm may also vary. For example, when we observe changes in the spot price of gold, expected future prices of gold presumably also change. When multiple prices simultaneously change, the theoretical convexity result has a natural generalization: maximized value \( V \) is now an upper envelope of hyperplanes rather than of straight lines. This implies the well known:\(^4\)

**Proposition 1.** Consider a firm that maximizes value \( V \) taking as given (input and output) prices \( p \equiv (p_1, \ldots, p_N) \). The maximized value \( V(p) \) is a convex function of the vector \( p \).

\(^3\) Strictly, the slope of the value function is the discounted value of the anticipated movement in future prices times outputs at those future dates, ignoring hedging. Comparing the estimated slope to reported reserves, while not directly related to our hypothesis, might seem a natural consistency check; but our industry and government contacts encouraged us to put little faith in firms’ reported economic reserves, as we discuss further later.

\(^4\) For an accessible statement see e.g., Kreps (1990). The earliest published source we have found is Gorman (1968); see also McFadden (1966). Daniel McFadden (personal communication, 2006) reports that the result goes back to the nineteenth century.
If we observed the entire vector $p$ of relevant prices, this proposition would let us test directly for value-maximization. Also, prices that do not change can of course be dropped from the price vector. However, some omitted prices may well vary in the sample. Indeed, what we do empirically below is track the empirical relationship between one price — “the” price, $p_g$, of gold, the primary output — and the stock market’s assessed equity value of the firm. How is this relationship affected if other, excluded, prices change in a way that is correlated (in the sample) with $p_g$? We address two versions of this question. First, we consider prices that the firm and investors can observe, but that we omit from our regressions. Second, we consider future prices that are uncertain at the observation date.

**Omitted (Known) Prices.** The effect of omitting a relevant price that is observed by market participants at the observation date differs according to whether it is linearly or non-linearly related to the included price(s).

Suppose first that certain excluded prices are linearly related to $p_g$ in the sample. Then the price vectors in the sample lie on a straight line in price space, and the observed function $\hat{V}(p_g)$ is the slice of the convex value function $V(p)$ that lies above that straight line. Consequently, $\hat{V}$ is convex along that straight line, and empirically will appear convex as an apparent or reduced-form function of $p_g$ alone.

In particular, of course, a gold-producing firm’s maximized value will depend on the future prices of gold. As just noted, if those prices were deterministically and linearly related to our single spot gold price measure, $p_g$, convexity would still hold. Similarly, if the price of an input, such as skilled labor, changed linearly with the price of gold, theory would still predict a convex estimated value function, even if we omitted wage rates from our regressions.

The effect is a bit less clear if the relationship between omitted and included prices is non-linear. Suppose for simplicity that just two prices affect $V$, and examine the observed relationship between $p_1$ and $V$ when (1) $V$ is indeed a convex function of the full price vector $(p_1, p_2)$, and (2) $p_2 = f(p_1)$, where $f$ is nonlinear (but note that any causality
between $p_1$ and $p_2$ is not important here). Then the reduced-form or observed relationship between $V$ and $p_1$ will be $\hat{V}(p_1) \equiv V(p_1, f(p_1))$. To study the convexity of $\hat{V}$, we calculate:

$$
\hat{V}''(p) = V_{11} + 2f'(p)V_{12} + f''(p)V_{22} + [f'(p)]^2 V_{22}.
$$

[1]

Thus the observed relationship $\hat{V}$ will be convex unless

$$
f''(p)V_2 < - [V_{11} + 2f'(p)V_{12} + (f'(p))^2 V_{22}],
$$

[2]

where the expression in square brackets is positive by convexity of $V$ in the vector $(p_1, p_2)$. Thus $\hat{V}$ will still be convex unless $f(\cdot)$ is “sufficiently” nonlinear, $p_2$ is “sufficiently” important in $V$, and either $f$ is convex and good 2 is an input or else $f$ is concave and good 2 is an output. Of course, when $f$ is linear we recover the result of the discussion above.

**Uncertain (Future) Prices.** If some prices are uncertain and their distribution is unaffected by changes in the observed price $p_1$, then convexity follows because value can be expressed as an expected value:

$$
\hat{V}(p_1) = \int V(p_1, p_2) dF(p_2 | p_1),
$$

[3]

and this is a sum of convex functions of $p_1$ provided that the distribution function $F$ does not shift with changes in the observed price $p_1$. This argument holds however much or little the firm will be able to re-optimize as further information about currently unobserved prices arrives: that affects the shape of $V$ as a function of $p_2$, but that is irrelevant for this argument.

Harder questions arise if the distribution of unobserved prices varies with the observed price, as is likely, especially when the unobserved prices are future spot prices of gold. When the expected value of each future price moves linearly in the observed spot price, so that for instance $\mathbb{E}(p_{t+1} | p_t) = a + bp_t$, there is a natural intuition that convexity will carry over. $V$ is convex in future prices as well as in today’s price, and if expected future prices are linear in today’s price, one might expect $\hat{V}$ to be convex in today’s price. This argument would be just a special case of the analysis in equation [2] if the relationship
among prices were deterministic. It also goes through, by the previous discussion, if the
firm cannot respond to later news about future prices, because firm value is then linear
in these prices. But if the firm will be able to respond to future prices, the option value
resulting from the variability in those prices may vary with today’s price. For example,
imagine that extreme values of $p_1$ (high or low) correspond to low conditional variances of
future prices, so the conditional variance is an inverted U-shape as a function of $p$. If the
option value is an important part of expected profits in the second period, extreme values
of $p_1$ would then correspond to low expected second-period profits, and potentially to low
present values.

To investigate this problem, consider an illustrative two-period model. At the begin-
ing of period 1, the firm has a stock $S$ of ore. It learns the first-period price, $p_1$, and then
chooses first-period extraction (and sales), $x_1$. Its costs in the first period of extracting $x_1$
are $x_1^2/(2S)$, so its marginal cost is increasing linearly in $x_1$ and decreasing in total stock
or reserves. It chooses $x_1$ knowing the conditional distribution of the second-period price
$p_2$, and it knows that at the beginning of period 2, it will learn $p_2$ and will then choose
second-period output $x_2$, at cost $x_2^2/(2[S - x_1])$.

Given $x_1$ and $p_2$, $x_2$ maximizes $p_2 x_2 - x_2^2/(2[S - x_1])$, so second-period profits are
$(S - x_1)p_2^2/2$. Consequently, given $p_1$, $x_1$ maximizes

$$
\hat{V}(p_1, x_1) \equiv p_1 x_1 - x_1^2/(2S) + \delta(S - x_1)E[p_2^2|p_1].
$$

[4]

The reduced-form value function $\hat{V}(p_1)$ is of course simply $\max_{x_1} \hat{V}(p_1, x_1)$. By the
envelope theorem, $\hat{V}'(p_1) = \partial\hat{V}/\partial p_1$, so differentiating again,

$$
\hat{V}''(p_1) = x'_1(p_1) \frac{\partial^2 \hat{V}}{\partial p_1 \partial x_1} + \delta(S - x_1) \frac{d^2}{dp_1^2}E[p_2^2|p_1].
$$

[5]

From the implicit-function theorem, $x'_1(p_1)$ has the same sign as the mixed partial
derivative of $\hat{V}$. Consequently, $\hat{V}$ is convex unless $E[p_2^2|p_1]$ is sufficiently concave in $p_1$;
and $E[p_2^2|p_1] = (E[p_2|p_1])^2 + \text{var}[p_2|p_1]$, and the first term is convex in $p_1$ if price follows
a martingale. Thus, the observed value function will be convex unless the conditional
variance is quite concave.
In section IV below, we explore how the conditional variance changes with gold prices and, as casual observation might suggest, find no evidence of such concavity of the conditional variance. In fact, we find some evidence of the opposite: extremely high values of \( p_1 \) if anything correspond to high, rather than low, conditional variances. That is, gold prices are high in times of uncertainty. We discuss this empirically in section IV below.

B. Value Response and Fat Accumulation

We saw that value functions should be convex in price if firms maximize value. But many observers have suggested that firms accumulate fat when they become wealthy, and that fat grows as financial constraints loosen: see for instance Jensen (1986) and other work on agency and free cash flow, and earlier work by Leibenstein (1966). Fat that is an increasing and convex function of wealth could make the firm’s net-of-fat value \( V - F \) concave in the price of gold.

Consider a gold mining company that would have value \( V \) if operated with no fat. Its actual stock market value, \( S \), will be \( S = V(p_g) - F(V(p_g)) \), where \( F(V) \) is the present value of fat (profit dissipated through inefficiency), which we take to be a function of \( V \).

Differentiating with respect to \( p_g \),

\[
S'(p_g) = V'(p_g)[1 - F'(V(p_g))], \quad [6]
\]

which will have the same sign (presumably positive for gold-mining companies) as \( V'(p_g) \) if \( F'(V) < 1 \), i.e., fat does not consume more than 100% of marginal wealth changes to the firm. Differentiating [6] with respect to \( p_g \) gives

\[
S''(p_g) = V''(p_g)[1 - F'(V(p_g))] - V'(p_g)^2 F''(V(p_g)). \quad [7]
\]

Hence,

\[
\frac{S''(p_g)}{S'(p_g)} = \frac{V''(p_g)}{V'(p_g)} - \frac{F''(V)}{1 - F'(V(p_g))} V'(p_g). \quad [8]
\]

The first term on the right in [8] is the (non-negative) ratio of marginally economic reserves (those barely worth extracting at price \( p_g \)) to total economic reserves (all those
worth extracting at price $p_g$). The second term is a measure of the convexity of the fat function. If the fat function is sufficiently convex, relative to the firm’s real-option opportunity to reoptimize when $p_g$ changes (the first term in [8]), then $\frac{S^\prime\prime(p_g)}{S(p_g)}$ will be negative, making $S$ concave in price.

Therefore, if empirically $S$ is concave in $p_g$, rejecting simple versions of full maximization, this could suggest fat, or at least investor expectations of fat. It can also imply a lower bound on expected fat. Since

$$F(V(p_g)) \equiv V(p_g) - S(p_g), \quad [9]$$

we can differentiate and divide by $V'(p_g)$ to get

$$F'(V(p_g)) = 1 - \frac{S'(p_g)}{V'(p_g)}. \quad [10]$$

Now consider observations at two prices: a low price, $p_g^L$, and a higher price $p_g^H$, as in figure 2. Since theory tells us that $V'(p_g^H) \geq V'(p_g^L)$, and since we presume that fat increases in wealth and hence in price (i.e., $F'$ and $V'$ are positive), we have $V'(p_g^H) \geq V'(p_g^L) \geq S'(p_g^L)$, whence

$$F'(V(p_g^H)) = 1 - \frac{S'(p_g^H)}{V'(p_g^H)} \geq 1 - \frac{S'(p_g^H)}{S'(p_g^L)}. \quad [11]$$

This gives us an observable lower bound on the fraction of the marginal dollar of wealth gain from an increase in $p_g$ near $p_g^H$ that is dissipated as fat, i.e., the quantity $F'(V(p_g^H))$, or “marginal fat.” It is one minus the slope on the $S$ function at point B divided by the slope at point A. The bound is strictly positive when $S$ is concave so that $S'(p_g^H) < S'(p_g^L)$.

We also get an observable lower bound on the total rent dissipation. From convexity of $V$,

$$V(p_g^H) \geq V(p_g^L) + (p_g^H - p_g^L)V'(p_g^L). \quad [12]$$

Since fat is non-negative (so $V \geq S$) and, we assume, weakly increasing in wealth (so $V' \geq S'$), the right-hand side is at least equal to

$$S(p_g^L) + (p_g^H - p_g^L)S'(p_g^L), \quad [13]$$
so

\[ F(V(p_g^H)) \equiv V(p_g^H) - S(p_g^H) \geq (p_g^H - p_g^L)S'(p_g^L) - [S(p_g^H) - S(p_g^L)], \]  

[14]

and this lower bound on total fat at \( p_g^H \) is positive when \( S \) is concave.

Equations [11] and [14] let us use our empirical results to infer bounds on marginal and total fat. Because we do not observe \( V' \), we cannot estimate fat but only bound it, on the assumption that fat causes the concavity of \( S(\cdot) \). The lower bounds will underestimate fat if, as one would expect, \( V(\cdot) \) is strictly convex or if the firm has some fat even at \( p_g^L \) (that is, \( F(p_g^L) > 0 \) and \( F'(p_g^L) > 0 \)). Of course, these supposed lower bounds will overestimate fat if concavity is caused by other factors such as those we discuss in section IV.

This theory of fat accumulation is obviously related to a free cash flow view of managerial behavior, but there are important differences. First, whereas empirical work on free cash flow relies on accounting measures, our approach uses an exogenous shock that changes the firm’s wealth, and works through investors’ responses to those shocks. Because it incorporates investors’ expectations, our approach may better attribute changes in firm behavior as a result of wealth changes that do not quickly affect cash flow. For instance, an increase in the price of gold may lead to management decisions — committing to higher wages, establishing attractive pension plans, planning new capital investments — whose main financial consequences may predictably arrive many years later. Thus, while our approach does not allow direct estimation of fat, it incorporates information that is missing, or mistimed, in free cash flow analysis. Neither is an ideal diagnostic tool, but each sheds some light on the issue.

III. Gold Prices and the Valuation of Gold Mining Companies

The gold mining industry is attractive for studying the effects of wealth changes on corporate fat, because there are frequent shocks to the price of gold that are exogenous to the gold mining companies we study, and those shocks translate directly into wealth shocks for gold mining firms.

Gold mining companies view themselves as price takers in the gold market. The mar-
ket for gold is worldwide, due to the metal’s high value-to-weight ratio and homogeneity, and no producer controls a large share of the annual extraction of new gold. More importantly, final demand for gold can be fulfilled from existing stock. Annual production of gold from mines worldwide is about 2% of existing stock of the metal. Thus, unilateral market power appears to be absent. Coordinated oligopoly interactions seem extremely unlikely given the large number of diverse gold mining firms and other holders of gold.

For the analysis outlined in section II to apply directly, changes in the price of the important input or output should be exogenous to the firms observed. This means not only that no firm has market power, but also that price movements are not driven by aggregate shocks to the observed firms, such as new gold discoveries by them or revisions in their estimated reserves. In fact gold price changes are almost uniformly the result of demand-side news: world events that change the attractiveness of gold as a store of wealth, trends in the demand for gold jewelry, or policy decisions of central banks to hold more or less gold. We searched the Wall Street Journal over the 28-year span of our sample for articles about gold prices and found almost no mention of gold supply (from gold mines) as a cause of gold price changes. Discussions with investor relations personnel at several gold mining companies also failed to uncover cases in which supply shocks from mines were thought to have significantly affected prices. Even the fraudulent Bre-X incident in May

5 The largest producer in 2004, Newmont Mining, reported 219 tons of production, about 9% of world production. Newmont claims 2900 tons of gold reserves, about 7% of world reserves.

6 According to U.S. Geological Survey data, existing stock is 128,000 tons and annual production is about 2500 tons. See http://minerals.usgs.gov/minerals/pubs/commodity/gold/gold_mcs05.pdf.

7 In an earlier exploration of this topic, Borenstein and Farrell, 1996, we analyzed the value response of oil companies to changes in the price of oil. We now analyze gold instead because it avoids a serious problem in doing the exercise in oil. Even if one assumed that there was no market power — a less compelling assumption than in gold — and ignored the complexity resulting from the fact that these companies were also in the oil refining business, an alternative explanation for a concave value function remained. The shocks we observed to oil prices were mostly (expected) supply shocks, and in many cases shocks to the supply of some firm in our sample. In that case, the price movements would be movements along a demand curve. If total revenue were concave in price along that demand curve, as seems quite possible, then the aggregate value of firms in the sample would very likely be concave in the price of oil. This points out the importance of analyzing shocks that are exogenous to the firms that we are studying.

8 One could of course regard these central banks’ decisions as supply shocks, but they are not shocks to the supply of the firms we study.
1997, in which an area of Indonesia that had been touted as the largest gold find in history turned out to have no economic supplies, did not significantly affect the price of gold.\(^9\)

The value of a gold mining firm should depend on spot and all information about future prices of gold, but we analyze the relationship empirically using one (near-term futures) price. While we subject this assumption to robustness tests below, we believe it is sensible because the prices move together very closely. Gold is actively and thickly traded and can be stored cheaply (relative to its value), so arbitrage would be comparatively easy if traders detected systematic departures from a martingale. Indeed, Augmented Dickey-Fuller tests using our weekly gold price series for 1977–2004 fail to reject a unit root.\(^10\) This is consistent with the findings of Pindyck (1993). Selvanathan (1991) found that a random walk hypothesis performed better than a panel of gold price forecasters. Figure 3 shows the price of gold over our sample period (in constant 2004 dollars), and Table 1 gives descriptive statistics.

To analyze the effect of gold prices on a gold mining firm’s stock market value one wants to control for market-wide stock price movements, which may represent, among other things, interest-rate changes or expected changes that would affect gold mine stock prices directly.\(^11\) Thus, we begin with the standard CAPM market model of equity returns:

\[
R_{it} = R_{ft} + \beta_i (R_{mt} - R_{ft}) + \epsilon
\]

where \(R\) is the rate of return, the \(i\) subscript refers to the observed firm, the \(m\) subscript refers to the market, and the \(f\) subscript refers to the riskfree rate of return. We multiply both sides of [15] by the stock value of the firm at \(t - 1\) to get the equation in terms of the

\(^9\) On May 6, while the stock of Bre-X fell 97% in value (confirming that the lack of economic supplies was news to the market), the price of gold fell about $2/oz.

\(^10\) The test statistic is -2.09 and the 95% critical value is -3.12.

\(^11\) Over our sample period, the correlation between the return on the market index and the return on gold futures is about 0.05, which is significantly different from 0 at the 5% level.
change in firm value:

\[ R_{it}S_{it-1} = \Delta S_{it} = R_{ft}S_{it-1} + \beta_i(R_{mt} - R_{ft})S_{it-1} + \epsilon S_{it-1}, \]  

[16]

where \( \Delta \) indicates the difference between the period \( t \) and period \( t-1 \) value of the variable.

We then specify explicitly the effect of the price of gold, which would otherwise be included in the error term.

Recall that we are interested in the curvature of the relationship between \( S \) and \( p_g \). This might be measured by the second derivative of a levels equation. Since our equation is in differences, we include the difference/derivative of a quadratic relationship between stock value and the price of gold. That is, if \( S = \gamma_0 + \gamma_1 p_g + \gamma_2 p_g^2 \), then \( dS = \gamma_1 dp_g + 2\gamma_2 p_g dp_g \).

So, we estimate the equation

\[ \Delta S_{it} - R_{ft}S_{it-1} = \alpha_1 \Delta p_{gt} + \alpha_2 p_{gt-1} \Delta p_{gt} + \alpha_3 S_{it-1}(R_{mt} - R_{ft}) + S_{it-1} \epsilon, \]  

[17]

where \( S \) is the stock market value of the firm, \( p_g \) is the price of gold, \( R_{mt} \) is the return on a value-weighted stock market index, and \( \alpha \)'s are parameters. In this model, \( \alpha_3 \) is the estimate of the CAPM \( \beta \). The coefficient \( \alpha_2 \) indicates the convexity (if \( \alpha_2 > 0 \)) or concavity (if \( \alpha_2 < 0 \)) of the relationship between the price of gold and the value of the firm.

We examine the stock market values of 17 gold mining companies that are traded in the U.S or Canada. We arrived at this dataset by examining lists of U.S. and Canadian gold producers and including each firm that (a) produced at least 10,000 ounces of gold in 1996, (b) mined gold predominantly or exclusively in the U.S., Canada, and Australia (we

---

12 We focus on just the equity value of the firm. As we discuss in section IV.C, this should strengthen the predicted convexity.

13 Using an equally-weighted index instead changes the results minimally.

14 Equation [17] does not include a constant term. We also estimated the equation with a constant term and found practically identical results. Similarly, since theory dictates that the coefficient on \( R_{ft}S_{it-1} \) is 1, we subtract this term from both sides of [16]. Including this term on the right-hand side and estimating an unrestricted coefficient makes virtually no difference in the results, though it does yield very noisy estimates on the riskfree rate term.
used this criterion to minimize the effect of political risk), (c) was primarily in the gold mining business, and (d) was publicly traded and is covered by the CRSP stock market data. This produced 21 firms. We then eliminated 4 firms for which fewer than 104 weekly stock observations (2 years of observations) were available. For all 17 firms used in the analysis, estimation of [17] with just a linear gold price term indicated that the value of the firm has a positive and statistically significant relationship to the price of gold.

Our full sample period is weekly observations for January 1977 through December 2004, a total of 1458 weeks. No firm is in the sample for the entire period, however. Some firms came into existence after 1977, while others were delisted, and ultimately ceased to operate, prior to 2004. Some firms have recently diversified and gold mining has become a relatively small share of their operations, so we drop recent years of operations for these firms. A few firms also made major purchases of other gold mining companies in the late 1990s and early 2000s.

The stock market values are taken from CRSP data. We use the nearest-contract gold futures price (traded on the COMEX division of the New York Mercantile Exchange) to represent the price of gold. While that contract changes every other month, our $\Delta p_{gt}$ variable is always the change for a given contract, not a comparison of prices on two different contracts. For the riskfree rate, we use the one-year T-bill yield on the day of observation transformed to a weekly interest rate. For each company we use weekly observations (closing price on the last trading day of each week) to estimate the value of the firm as a function of the price of gold.

Since we expect rent dissipation or fat to depend on the firm’s real wealth, we deflate all variables. We deflate $S, p_g$ and the market index on which $R_m$ is based to 2004 dollars using the consumer price index (all items – urban consumers). We translate the nominal

---

15 We drop from the sample the weeks of 9/10/2001, 9/17/2001 and 9/24/2001 due to the September 11, 2001 terrorist attacks, which disrupted financial markets.

16 We include weeks in which the stock goes ex-dividend or the number of shares outstanding changes, but adjust firm valuation for these changes. Dropping these weeks results in the loss of about 10% of all observations and has virtually no effect on the results.
The t-bill yield used for $R_f$ to a real yield by $R'_f = \frac{1+R_f}{1+\pi} - 1$, where $\pi$ is the inflation rate calculated from the CPI for the month of the observation.

The error term in the regression we estimate may be heteroskedastic, both because the equation is in terms of the value of the firm (as indicated in [16]) which changes over time, and because exogenous factors affect the volatility of stock market returns. We address this problem by estimating the regression using GLS, explicitly controlling for heteroskedasticity caused by the presence of $S_{t-1}$ in the error term. We do the GLS estimation by dividing both sides of equation [17] by $S_{t-1}$. We then report White heteroskedastic-consistent standard errors to control for other heteroskedasticity. We have also carried out the analysis without the GLS correction, but just implementing the White correction to the standard errors, with qualitatively similar results, as we show below.\(^{17}\)

**A. Estimation of a Quadratic Value Function**

We begin by separately estimating [17] for each of the 17 firms by GLS. The sample periods differ across firms, but each regression includes at least 287 observations and the median number of observations is 911. The results are shown in table 2. The estimated second derivative is negative for 11 of the 17 firms, and significantly negative (at the 5% level) for 8 of them. Of the 6 estimated positive second derivatives, only 1 is statistically significant. The \(z\)-statistic for the 17 estimated second derivatives is \(-27.54\) with a standard error of $\sqrt{17} = 4.12$, which is significant at the 1% level. Thus, we find a *concave* relationship between the price of gold and the values of many of the gold mining firms.

The other parameters estimated are reasonable and consistent with expectations. The implied first derivative of stock market value with respect to the price of gold is positive for each firm at the median price of gold in the sample and is positive for nearly all gold price values that occur while the firm is in the sample.\(^{18}\) The CAPM $\beta$ parameter estimated for

\(^{17}\) There is also a potential econometric issue of cointegration of firm value and the (nearest contract) futures price of gold. We tested for cointegration and found that in all cases, the null hypothesis of no cointegration was strongly rejected: t-statistics above 18 in all cases compared to a critical value that varies with number of observations, but is around 3.

\(^{18}\) The implied derivative at a given price of gold $p_g$ is $\alpha_1 + \alpha_2 \cdot p_g$. 

14
these firms vary, but is significantly below 1 in all cases.\textsuperscript{19}

To interpret the magnitude of the curvature of the estimated value function, we create a benchmark slope for each firm in its lean state. We calculate the estimated slope of each firm’s value function when the price of gold is $409.15, its 25th percentile value in the full 28-year sample. We then calculate by how much the slope is estimated to change when the price of gold increases to $501.55, its median value in the full sample. These figures are given in the first columns of table 3.\textsuperscript{20}

Graphically, this calculation compares the slope at point B to the slope at point A in figure 2. In terms of our equation \[11\], this is \( S'(p^H_g)/S'(p^L_g) - 1 \). For Campbell Resources, for example, if the statistically significant 5.6\% estimated decline in the slope were precise and were due solely to fat, this would suggest that when the price of gold increases slightly starting from its median level, at least 5.6\% of the incremental gain is dissipated, \( i.e., \) is not reflected in increased shareholder wealth. Recall that, taking the point estimate as correct and assuming all concavity is due to fat, this is a lower bound, since the \( V \) function is (weakly) convex.

The \( z \)-statistic discussed above is one way to aggregate our data across firms. Another is to study the response of a portfolio of gold mining firms to changes in \( p_g \). We do this by taking a weighted average of the slopes of the value functions, with each firm’s weight being its average market capitalization while it is in the sample. We then again calculate how the slope of \( S \) is estimated to change if \( p_g \) rises from its 25th percentile to the 50th percentile value, as a percentage of the slope when \( p_g \) is at its 25th percentile. The result is an estimated decline of 11.5\%, and is significant at the 5\% level.\textsuperscript{21}

\textsuperscript{19} Using an equally-weighted, rather than value-weighted, market index moves the \( \beta \) estimates for all firms closer to 1, but otherwise has minimal effects on the results. We have also estimated the \( \beta \)s without the gold price terms, which results in very similar estimates as when the gold price terms are included.

\textsuperscript{20} The estimated changes from an OLS regression with heteroskedastic-consistent standard errors are shown in the second column of table 3. The qualitative results are the same.

\textsuperscript{21} The variance of this estimate is calculated on the assumption that the estimates for each firm are statistically independent.
If this concavity were due solely to fat, our estimates would also imply a lower bound on the *total* fat that accumulates when \( p_g \) increases, as a proportion of the theoretical increase in wealth; in figure 2 this proportion is \( \Delta F/\Delta V \). Even if the firm is fat-free when \( p_g = 409.15/\text{oz.} \), the aggregate estimate for the 17 firms would imply that at least 5.7% of the potential wealth gain when the price increases to $501.55 is not realized or at least not passed to shareholders.

**B. Estimation of a Piecewise-Linear Value Function**

Estimating a quadratic value function is a natural starting point since we are interested in the curvature of the relationship, but the quadratic is quite restrictive. As an alternative and a sensitivity test, we also estimated a piecewise-linear relationship between \( S \) and \( p_g \), with breaks at the 25th and 75th percentiles of the distribution of \( p_g \).\(^{22}\) To accommodate tests of slope differences, the regressions are run with a slope term in effect over all prices (\( \Delta p_{gt} \)), and additional slope terms that apply only for prices in, respectively, the lowest (\( \Delta p_{L}^{L} \)) and highest (\( \Delta p_{H}^{H} \)) quartiles of the gold price distribution. The equation we estimate is:\(^{23}\)

\[
\Delta S_{it} - R_{ft} S_{it-1} = \alpha_1 \Delta p_{gt} + \alpha_2 H \Delta p_{H}^{H} + \alpha_2 L \Delta p_{L}^{L} + \alpha_3 S_{it-1} (R_{mt} - R_{ft}) + S_{it-1} \epsilon. \tag{18}
\]

The results, shown in table 4, are consistent with the quadratic estimation. For 6 of the 17 firms the slope in the lowest quartile of gold prices is estimated to be significantly (at the 5% level) steeper than in the middle range of prices, indicating concavity. In one case the slope is significantly flatter in the lowest quartile than in the middle range of prices. For 6 of the 17 firms, the slope in the highest quartile of gold prices is estimated to be significantly (at the 5% level) flatter than in the middle range of prices, indicating concavity, while it is not significantly steeper in the highest quartile for any firm. An F-test of whether \( \Delta p_{L}^{L} = \Delta p_{H}^{H} \) indicates that the slope is significantly (at the 5% level) smaller in

\(^{22}\) For each regression we used the 25th and 75th percentiles during the time the firm is in the sample, rather than the values shown in table 1.

\(^{23}\) Thus the estimated coefficient on the highest quartile is \( \alpha_1 + \alpha_2 H \) and the estimated coefficient on the lowest quartile is \( \alpha_1 + \alpha_2 L \).
the top quartile than in the bottom quartile for 10 firms (8 of which indicated significant concavity in the quadratic function estimation) and the slope is not significantly different between the quartiles for the remaining 8 firms.

The percentage difference between the estimated slope in the top quartile and the estimated slope in the bottom quartile is presented in the right-hand column of table 4. The unweighted average of this statistic across the 17 firms is 39% less slope in the top quartile than in the bottom quartile. Thus, again there is strong evidence that for many of these firms the slope of the $S$ function is greater when gold prices are low than when they are high.

IV. Alternative Explanations for Concavity

Having found significant concavity for a number of firms in our sample, we are tempted to infer that these firms do not always maximize profits given the prices they face, and in particular that increases in wealth will be partly dissipated in inefficiency, or at least that is what investors expect. There are, however, a number of potential alternative explanations.

A. Progressive Corporate Profits Tax

The progressive corporate profits tax in the U.S. — broadly, zero tax when the firm has negative earnings and a linear rate of 34%-48% (varying during our sample period) when it has more than minimal positive earnings — might explain some concavity in the $S(p_g)$ function, by making after-tax flow profits a concave function of pre-tax flow profits.\textsuperscript{24} To consider an extreme possibility, suppose that at low values of $p_g$ a marginal pre-tax dollar is untaxed, while at high levels it is taxed immediately at rate $t$. Then taxes reduce the slope of the flow-profit function at high gold prices by a factor $1 - t$, while having no effect at low gold prices.

This calculation is misleading, however, because firms can carry forward losses to offset profits. To illustrate starkly, consider another extreme possibility: suppose that

\textsuperscript{24} Tax policies and rates in Canada and Australia are fairly similar to those in the U.S., so this discussion applies to nearly all of the tax liabilities of the firms in the sample.
(1) positive profits are taxed at 48% each year and negative profits have no tax liability, (2) losses always can be carried forward long enough to offset future profits, and (3) the discount rate is zero. In that case, all firms would pay 48% on their net (over time) profits. Any change in wealth from a change in the price of gold would be taxed at 48% regardless of the level of gold prices: this would lower the slope uniformly but would not affect convexity or concavity, as measured by the ratio of slopes at various gold prices.

In fact, the tax code is much more complex. In particular, tax losses can be carried forward only for a limited amount of time, and lose value when carried forward, because of (time) discounting. Tax losses can also be carried backward. In addition, investment tax credits, opportunities for arbitrage (as when a firm with tax losses and a firm with tax profits merge), and international tax treaties greatly complicate the analysis. Still, because a firm can smooth taxable income across years, its marginal tax rate is likely to vary much less than a simple view of the corporate profit tax schedule would suggest.

Altshuler and Auerbach (1990) examine the effect of the tax schedule’s nonlinearity on the marginal tax rate that corporations in fact face. They find that at a time when the tax schedule suggested a marginal corporate tax rate varying between zero and 46%, the effective expected marginal tax varied cross-sectionally from 18.9% to 38.6%.

Even if $V$ were linear and if higher tax rates in the Altshuler-Auerbach range were systematically associated with higher gold prices, this could explain at most a proportional decline in after-tax slope from $1 - 0.189 = 0.811$ to $1 - 0.386 = 0.614$: that is, it could at most make the slope at the highest gold price $[0.811 - 0.614]/0.811 = .25$, or 25% lower than the slope at the lowest gold price. This would be substantial, but comparing the righthand column of table 4, which gives the estimated change in slope from the bottom to the top quartile, suggests that this would not explain the magnitude of concavity we find. For all of the 10 firms in which the slopes differ statistically significantly between the bottom and top quartile, the slope in the top quartile is more than 25% lower than the

---

25 They study all non-financial corporations, not specifically gold mining companies. They account for investment tax credits, credits for foreign income, and a number of other complexities of the tax code.
slope in the top quartile.

But tax convexity seems unlikely to explain even as much as this 25% quasi-bound, for two reasons. First, it would be surprising if a change in gold price were to move a single firm from Altshuler and Auerbach’s minimum to their maximum estimated effective tax rate: the reported variation is across all firms in the sample, including agriculture, mining, construction, manufacturing, transportation, trade and services, so the variation over time for a firm in just one industry is likely to be smaller. Second, as Graham and Rogers (2002) note, the tax code is most apt to make (present-value) after-tax profits concave in pre-tax profits where (flow) profits are teetering near zero. Since we study equity value, not total firm value, the option value of bankruptcy should tend to make equity substantially convex in total firm value in just those cases where taxes would otherwise have the most effect on the shape of the value function.26

As Graham and Rogers (2002) also discuss, hedging can further mitigate any tendency for the tax code to tax a firm’s good years while not subsidizing its bad years. More generally, the firm’s maximized after-tax value should be an upper envelope of (perhaps concave) functions of the price of gold, not simply an after-tax version of the upper envelope of straight lines as described in section II above.

Finally, the possible value concavity due to taxes changed significantly after 1986, when a change in the U.S. tax law made it much more difficult to carry losses backward and forward. Columns (5) and (6) of table 3 show results when the sample period is broken into 1977-1986 and 1987-2004. If the concavity were due primarily to taxes, we would expect to find more concavity in the latter part of the sample. In fact, of the 7 firms for which we have enough data to estimate in both periods (we restricted to at least 104 observations in each period), the value function is significantly less concave after 1986 in 3 cases, significantly more concave in one case, and not significantly different in 3 cases.

---

26 One might perhaps imagine a firm that is not near bankruptcy even though it is teetering near zero flow profits in the medium term. However, three firms in our sample actually filed for Chapter 11 bankruptcy protection during our sample period and one other was de-listed from the NYSE for failing to meet minimum capitalization levels.
B. Omission of Relevant Correlated Prices

We noted in section II that if an important price were non-linearly related to \( p_g \), a spurious concave relationship between firm stock market value and the price of gold we examine could arise. For instance, if the ten-year-out futures price of gold were concave in our gold price regressor \( p_g \), our reported results could obtain even if \( S \) were convex in the two prices jointly (as optimizing theory predicts it should be).

Unfortunately, futures prices for gold did not generally exist for delivery more than two years in the future during part of our sample period. The longest contract for which prices are available throughout our time frame is that for delivery 12–14 months in the future (for delivery one year later than the delivery month of the nearest contract). Still, if important “implicit” futures prices were concave in \( p_g \), one would expect to see some indication of this in a contract for a claim more than a year in the future.

The simplest approach to testing this explanation would be to include both this more distant futures price and the nearer futures price in the regression. These prices, however, are so highly correlated that doing so increases the standard errors of the estimates to the extent that the estimated second derivatives could not be statistically distinguished from zero or from the estimates that we had obtained without the more distant futures price.\(^\text{27}\)

An alternative approach, however, produces evidence against this explanation for concavity. If distant future prices are concave in nearby future prices, it follows that nearby future prices are convex in long future prices.\(^\text{28}\) Thus, omitting the nearby future gold price and using only the more distant future gold price would be omitting a price that is convex in the included price and would lead to an overestimate of the convexity of the stock price function. We examined this using the 12–14 month out futures price. The slope changes implied by these estimates and their standard errors are shown in column

\(^{27}\) As stated earlier, augmented Dickey-Fuller tests on the 1977–2004 gold price series cannot distinguish the behavior of gold prices from a random walk. Of course, longer-term mean-reverting behavior is very difficult to diagnose and investor beliefs about mean reversion even more so.

\(^{28}\) We are discussing the actual relationship between these prices, not an estimated statistical relationship, for which this statement might not hold.
(3) of table 3. It is apparent that this substitution makes very little difference in the results, though it might be causing all estimates of second derivatives to be closer to zero. The estimated concavity of the aggregate portfolio implies that an increase in price from the 25th percentile to the sample median price of gold would decrease the slope of the aggregate $S$ function by 9.4%. While that is smaller than the 11.5% we estimated when using the nearest futures price, the difference is much smaller than one standard error of either estimate. Using a futures price that is a year further in the future and omitting the next-to-nearest contract price does not make the estimated $S$ functions substantially more convex.

Finally, with the nearby and more distant futures price series, we can test directly for a non-linear relationship between these prices. A linear regression of the 12–14 month out futures price on the nearest futures price and the square of the nearest futures price yields a positive and significant parameter estimate on the second order term, though the effect is quite small. Omission of this futures price would thus tend to cause a bias towards finding convexity. Thus, neither of the tests we have carried out indicates that the concavity we find is a result of nonlinearity in the relationship between nearby and more distant futures prices of gold.

The other potentially important omitted output price is the price of silver. Most gold producers also mine some silver since deposits are often co-located. Of the 17 firms in our sample, 6 exhibit a positive and statistically significant first-order effect of silver prices on firm value in a regression with changes in prices of both gold and silver. Column (4) of table 3 presents the estimated convexities/concavities (in gold price) after adding

---

29 This reflects the fact that gold prices are highly correlated with the interest rate — a 0.73 correlation in our sample — and future gold prices exceed spot prices by nearly exactly the nominal interest rate at all times due to an arbitrage condition.

30 Some readers have suggested that mean reversion in the price of gold might produce concavity in $S$. We doubt that there is systematic mean reversion: it would imply profitable arbitrage opportunities, and the empirical evidence mentioned earlier is that a random walk is consistent with gold price movements during our sample. But in any case, mean reversion is just a special case of the omitted price analysis, where the omitted prices are the future prices of gold. For an omitted output price to explain the concavity we find, it would have to be concave in the included price, and (as discussed in the text) we find no evidence to support this.
first- and second-order silver terms to the estimation of equation [17]. While this changes the estimated second-order effects of gold price changes somewhat, it does not affect the finding that the majority are concave in gold price. $S$ is still estimated to be a concave function of the price of gold for 12 of the 17 firms; for 7 of those the second derivative is statistically significant at the 5% level. Also, for 12 of the 17 firms our estimates imply that firm value is concave in the price of silver; for 5 of those, the effect is statistically significant at the 5% level.

Omitted input prices could also potentially be important. If the industry faced increasing marginal costs of some input, then potentially this could transfer (rather than dissipate) the rents generated from high gold prices. *Firm*-level increasing marginal cost does not have this effect: even if the firm’s marginal exploration project is much more expensive than inframarginal projects, it is still true that the firm can continue to do at a higher $p_g$ what it was doing at a lower $p_g$, so the upper-envelope result still holds. Even if the input price effect is an industry-level effect, however, we do not believe this is likely to be very important, for three reasons.

First, the industry executives we talked to did not think it plausibly important (although they did suggest that geologists are better paid when gold prices are high).

Second, changes in the price of assets that the firm owns would not explain observed concavity. For instance, increases in the price of gold presumably raise the market value of land on which the gold mine is located, but that cannot lead to concavity of the $S$ function if the mining firm owns the land. Changes in the market value of an owned asset do not affect the basic argument that the firm could continue to use the same production plan — the upper-envelope argument that implies convexity of $V$.

Third, and perhaps most important, even if in the short run the industry-level supply curve of some inputs (such as geologists) were sharply upward-sloping, so that an increase in $p_g$ would make even inframarginal exploration much more costly in the short run, it is hard to believe that the *long-run* supply curve of geologists is so steeply upward-sloping as it would need to be to explain our results. Because we examine the effects of changes
in $p_g$ on the stock market estimate of the present value of profits, effects that apply to current-year or near-term future profits but not to further-out profits will have limited effect on our results. This is particularly true in a competitive extractive industry such as gold mining, where cutting output during an input-price spike would not sacrifice output in the long run, but only postpones it.

C. Debt

While the theory concerns the overall (asset) value of the firm, our empirical implementation actually tracks the firm’s equity value. However, since equity is a call option on the underlying assets (equity holders can own the assets by paying the debt), the value of equity is convex in the value of the assets, so if the latter is convex in $p_g$, so is the former.31 This shows that the presence of a given amount of debt could not falsely generate concave estimated $V$ functions.

A more subtle possibility would be that firms take on different amounts of debt over time, in a way that is correlated with $p_g$ in the sample. In principle, this could create a spuriously concave equity function. However, we believe that in practice the bias would go the other way. When $p_g$ rises, the increase in the firm’s asset value, $V'(p_g)$, is divided between debtholders and equityholders. The fraction of the increase that goes to equity holders is the probability $p(p_g)$ that debtholders will be paid off, i.e., that the firm will not enter bankruptcy. So we are estimating the slope of $p(p_g)V'(p_g)$ as a function of $p_g$. Its derivative is $pV''(p_g) + p'(p_g)V'(p_g)$, which is positive (on the assumption of no fat) provided that, as theory implies, both $V'$ and $V''$ are positive and provided that $p'(p_g) \geq 0$. In other words, to find spurious concavity of the empirically estimated $V$ for this reason would require that firms take on so much more debt when $p_g$ is high that they are then significantly more likely to go bankrupt than when $p_g$ is low. This seems very unlikely.32

---

31 We thank an anonymous referee for this elegant argument.

32 Related to this discussion of debt is the possible effect of imperfect capital markets. If firms had to finance new exploration internally because external capital was unavailable, then increases in the price of gold would create financing for new investments, investments that would have progressively lower rates of return (though still greater than outside-the-firm investment options). This could result
D. Changing Variance in Gold Prices

In section II, we noted that the stock market value of a maximizing firm might be concave in $p_g$, the current price of gold, if the real option value of gold mining, which increases with the variance of future spot gold prices, were a concave function of $p_g$. As we showed there, however, this could happen only if the conditional variance of future spot prices were a strongly concave function of $p_g$.

We addressed this concern by estimating the relationship between the level and the expected future variance of gold prices. For every observation, we calculated the sample variance of the next 26 weekly gold price observations (for the next-to-nearest gold futures contract). We then regressed this measure of actual future variation in gold price on a constant, $p_g$, and $p_g^2$, using 56 observations spaced six months apart over the 28-year sample period. We found that actual future variation of gold prices is estimated to be a convex function of $p_g$, but is not statistically distinguishable from a linear (increasing) function.

E. Hedging by Gold Mining Firms

Many gold mining firms trade in the gold futures market in order to hedge the risk associated with gold price movements.\textsuperscript{33} Tufano (1996, 1998) finds substantial diversity in hedging among gold mining firms.\textsuperscript{34} He describes two types of financial hedging that are common in the industry: linear strategies, such as selling gold forward, which reduce the

\begin{itemize}
\item\textsuperscript{33} One executive we spoke with said that when banks lend to a gold mining firm, they often require or prefer this.
\item\textsuperscript{34} Tufano (1998) also explores the relationship between gold prices and firm values, but focuses on rate of return or percentage changes. He shows that a mining stock would be \textit{proportionally} less sensitive to the price of gold when the gold price is high than when it is low, if the firm has no flexibility in its production plan, because (as his equation (2) confirms) the value of the firm would be linear in the price of gold.
\end{itemize}
firm’s overall exposure to changes in gold prices, and non-linear strategies, which consist largely of buying options, usually put options.

Holding put (or any other) options will convexify $S$. As for linear strategies, when a gold mining firm sells gold forward at a fixed price, this of course flattens out the firm’s $V$ (and presumably its $S$) function; in effect, the firm has already sold some gold, and so now owns less of it, reducing the slope of the $V$ (or $S$) function. But such a linear strategy considered in isolation should not affect concavity or convexity. A *pattern* of linear strategies, however, could in principle concavify $S$, if firms in our sample effectively owned less gold when gold prices were high than when they were low. Such a correlation would make their $V$ functions flatter at high gold prices than at low gold prices, so that finding a concave $S$ does not show that $S$ departs from $V$.\textsuperscript{35}

Unfortunately, because Tufano’s data covered only a relatively short time span, we cannot infer whether such a pattern happened to occur; and he showed that firms’ risk management practices were changing, so it is difficult to infer whether firms pursued *strategies* that would cause such a pattern, *i.e.*, hedge more when gold prices are high.\textsuperscript{36} Of course, implementation of such a strategy would require knowledge of when prices are high relative to the level they will be in the future, which is at odds with a finding of prices following a random walk.

To address empirically whether hedging patterns might cause concavity, we examined firms that engage in little or no hedging. Peter Tufano provided us a list of firms that engaged in no hedging activities in 1990 or 1992. Because our discussions with industry participants suggested that hedging has become more common over time, we assumed that

\textsuperscript{35} Selling call options would also tend to concavify the firm’s value function. There was some mention of this in our interviews with managers, and Tufano mentions it in his work, but it does not appear to be the primary form of hedging among gold mining firms.

\textsuperscript{36} A related issue is purchases and sales of mines which change a firm’s exposure to gold prices. In fact, mines (or shares of mines) are frequently sold among firms. We have found no evidence that the firms in our sample tend to sell mines when prices are high and buy them when prices are low, which would be necessary to explain the concavity we find. Furthermore, the firms we observe, in aggregate, display concave value, suggesting that such transfers among the firms in our sample do not explain the concavity we find.
such a firm did little or no hedging in previous years. Two firms on this list, Coeur D’Alene and Homestake Mining, were also in our dataset for at least four years before 1992. For those two firms, we re-estimated $S$ using only data from prior to 1992. In each case, the estimated second derivative terms were negative (concave $S$) and significant at the 5% level. The estimated proportional declines in the slopes of $S$ when $p_g$ increases from $409.15$ to $501.55$ are 6.2% for Coeur D’Alene and 5.4% for Homestake. These results are consistent with the results reported in section IV.A, when we broke the sample at the end of 1986. In the first 10 years of the sample, when hedging was reported to be less common among gold mining firms, we find strong evidence of concavity for six of the seven firms that are in our sample for that period.

Finally, Tufano and Serbin (1993) reports that the average North American gold producer hedged 9.6 months of output at the end of 1991. Our industry sources indicated that even today, firms seldom hedge more than the equivalent of a few years of their production, so most of their expected future production at any time remains unhedged, especially in light of the “replace your output” rule of thumb discussed below in section V.A. Thus, for both theoretical and empirical reasons, hedging practices are unlikely to cause concavity in the $S(p_g)$ function we estimate.

\section{Optimal Labor/Executive Compensation Contracts}

For incentive or risk-sharing reasons it might be optimal to give managers or workers equity or options in the company. Our analysis is unaffected if they hold equity, because the market value of the firm includes all shareholders. But if they hold options, this could concavify the (remaining) value function of the actual shareholders in the firm.

Similarly, if wages and salaries increase more than linearly with $p_g$ as part of an optimal labor contract (explicit or implicit), this could concavify $S$, because an increasing share of wealth gains from gold price increases would go to workers, rather than shareholders. Indeed, it would do so in a way very like the “fat” mechanism described above, although we might interpret it differently.
But it seems very unlikely that executive compensation tied to earnings could account for more than a trivial fraction of the large concavities we find in a substantial number of our sample firms. Gold mining companies pay a small fraction of firm value as executive compensation.\textsuperscript{37} This is not surprising, because a comparatively large share of firm value is represented by tangible, transferable assets. That is, much of the firm value is due to its holdings of land or rights to mine, not value creation by the firm’s operations. Furthermore, firm value changes are largely due to events (in this case, gold price shocks) that are exogenous to the firm. Incentive/compensation theory suggests that optimal compensation plans should not award managers a significant share of firm value changes that result from exogenous events.\textsuperscript{38}

To examine this possible explanation, we obtained executive compensation data for the five companies in our sample that are also in Compustat’s ExecuComp database.\textsuperscript{39} We constructed the total salary and bonus compensation (the “TCC” variable in ExecuComp), and the total compensation including option grants (the “TDC1” variable in ExecuComp\textsuperscript{40}) for the top 5 executives in the firm in each year.\textsuperscript{41} This yielded 42

\textsuperscript{37} For the five firms for which we obtained recent compensation data, described below, salary plus bonus of the top-5 (by salary) employees averaged 0.77% of sales and 0.25% of the equity value of the firm. Total compensation including value of new options issued averaged 2.3% of sales and 0.5% of the value of the firm.

\textsuperscript{38} Milgrom and Roberts (1992) call this the “informativeness principle.” It is possible that despite the (we believe greater than average) role of exogenous events in changes in firm value, shareholders might want to give managers strong incentives to respond efficiently to gold price movements by opening or closing mines (and perhaps overcome the managers’ own tendencies towards risk aversion). In this case, they might want to give some of the value change to managers. But, especially in view of how simple it would be to design a compensation scheme that neutralized at least a substantial part of the role of gold price changes, it would seem surprising if managers were given a large share of the value changes resulting from gold price shocks. See, however, Bertrand and Mullainathan (2001), for evidence that managers do get rewarded for luck.

\textsuperscript{39} The companies and the years they are in ExecuComp are Getchell (95-97), Echo Bay (94-01), Barrick (94-03), Placer Dome (94-04), and Glamis (94-03). ExecuComp begins in 1992, but the first two years of data are considered less reliable.

\textsuperscript{40} Defined by ExecuComp as “Salary, Bonus, Other Annual, Total Value of Restricted Stock Granted, Total Value of Stock Options Granted (using Black-Scholes), Long-Term Incentive Payouts, and All Other Total.”

\textsuperscript{41} Glamis lists only 4 executives for some of the years, so we took the sum of compensation for the top 4 listed by Glamis in each year.
company-year observations.

A log-log regression of the more expansive compensation variable (TDC1) on the firm fixed effects and the equity value of the firm exhibits the expected positive relationship, an estimated elasticity of 0.49 with a White heteroskedasticity-consistent standard error of 0.13. But the same regression using the price of gold instead of firm value yields a coefficient and standard error of -0.21 (0.45). As compensation theory would suggest, it appears that gold mining executives are not rewarded for gold price changes. When both firm value and gold price are included in the regression, the effect of gold price is significantly negative and firm value is significantly positive, suggesting that holding the value of the firm constant, compensation declines when the price of gold increases. These results are consistent with the idea that managers are compensated for the value of firm changes not driven by gold prices, but not for firm value shocks due to gold price changes.\(^{42}\) They suggest that it is very unlikely that executive compensation explains a concave relationship between gold prices and the equity value of the firm.

Mining labor costs are a much larger share of firm operating costs than executive compensation. In some industries, labor rent sharing has been suggested as a substantial effect when firms get wealthy. We discuss this in section V.

G. Environmental Liabilities

Gold mining firms, which are viewed as causing extensive environmental damage, might be required to pay disproportionately more for clean-up if they are relatively rich. Although environmental liabilities are non-trivial — one source put them at about 15 percent of “hard” costs — this is unlikely to explain the concavity we observe. According to our industry and government sources, most environmental legislation bearing on mining companies applies to all mining, not to specific sectors such as gold mining. Industry participants did not see clean-up costs or liabilities as being very much subject to discretion

\(^{42}\) When we use log of TCC, which includes only salary and bonus, as the dependent variable, the effect of firm value alone is insignificant positive and gold price alone is insignificant negative. With both regressors included, firm value again has a positive and significant coefficient and gold price again has a negative and significant coefficient.
or variation. Relatedly, when we mentioned this hypothesis to government regulators, they commented that it was an interesting idea, but that they were aware of no examples. Finally, for environmental liabilities short of bankruptcy to explain concavity, they would have to not only increase with the price of gold, but would have to be convex in the price of gold, i.e., the proportion of marginal wealth that would be allocated to additional environmental liability would have to increase with the price of gold. Finally, one could also ask about “asbestos-style” liabilities, which with some probability will bankrupt the firm. For such risks to cause concavity, however, the probability of a bankrupting liability would have to be significantly increasing in $p_g$.

H. Royalty Payments

Sometimes governments (or owners of auriferous properties who delegate the mining) demand royalties for gold extraction. A linear royalty schedule (whether on units, revenues, or profits), like a linear tax schedule, would not affect the predictions of convexity. However, royalty rates that increase with the price of gold (or with the total revenues attributable to a mine, for instance) could potentially cause concavity of the value function. Accordingly, we asked our industry and government contacts to comment on this possibility. Our discussions suggested that royalties are most often linear. Some royalties kick in above a certain point, and others are capped; thus some would contribute to concavity and others tend towards convexity. Some royalties are based on accounting net profits, but one well-informed commentator suggested that it is viewed as unwise for an agent who can extract royalty payments to take a percentage of the net, because doing so stimulates cost accountants’ creativity in undesirable ways, somewhat as it is said to do in the case of Hollywood movies.

We also note that the hypothetical examples this source used in discussing the matter with us had royalty rates of 1 percent or a few percent, except for one that was ten percent of accounting profits. Other industry sources also tended to come up with examples involving a few percentage points. This itself suggests that royalties as a whole are unlikely to be of a magnitude that could be driving our results.
Finally, Centurion is a company that specializes in exploration and royalty collection: it leases properties on which gold deposits have been found to mining companies and collects royalties. If it imposed more-than-linear royalties, one would expect its $S(\cdot)$ function to be correspondingly convex. In fact, our estimated $S$ function for Centurion was concave (although not statistically significantly concave).

I. Negative Correlation between Gold Price and Gold Reserves

The theory above, together with a Hotelling version of the random walk theory of gold prices, implies that $V'(p_g) = e(p_g)$, where $e(p_g)$ is the firm’s economic reserves of gold.\(^{44}\) The optimizing theory that we test assumes that $e$ is weakly increasing in $p_g$. While higher gold prices clearly make more gold economic to extract, this causal effect could be obscured if other factors induce a negative correlation between economic reserves and gold prices.

Such negative correlation could be just a fluke during our sample period: these companies might have happened to expand their reserves, either through new discoveries or purchase of other companies, at times when gold prices were declining. Less coincidentally, an industrywide improvement in exploration or extraction technology could increase the economic reserves of a typical firm, and also lower gold prices through an increase in (expected) market supply, though it seems unlikely that incremental changes in extraction technology will have a discernible effect on price. Or, when prices rise, mining firms might increase extraction of gold even more than they increase discoveries of new economic reserves, which would create a negative correlation of reserves (on which the company has claim) and prices.

In fact, the real price of gold trended downward from 1980 to 1999, which includes most of our sample period. The question then is whether economic reserves were moving

---

\(^{43}\) Centurion may have been in financial distress during this period; however, that should if anything bias results towards finding its value function to be convex (through the usual bankruptcy-option effect).

\(^{44}\) Note that this is the first derivative of the value function, which is not affected locally by the option value effect. Still, the value of $e$ would have to be adjusted for “anticipated finds” if some gold exploration projects that have not yet discovered all economic reserves at a location have strictly positive expected net present value on further exploration.
inversely to the gold price trend. Unfortunately, we have been unable to find consistent data on economic reserves by firm for most firm-years..

We collected data from a number of sources to get annual reserve figures for 38 firm-years covering 6 firms. Using these figures, we estimated [17] adding an additional term: \( \alpha_4 \text{reserves}_{it} \Delta p_{gt} \). This term allows the slope of the \( S \) function to vary with the reserves firm \( i \) holds at time \( t \).\(^{45}\)

When we estimate this modified equation by firm, the second order term is not significant for any of the firms. This seems due in part to the small number of observations and in part to the fact that reserves for most of the firms we observe move very little during the years we observe. As a result, the new variable is highly collinear with \( \Delta p_{gt} \). A test for pooling the observations across firms, however, does not reject pooling when the reserves interaction variable is included. In a pooled regression, the second order term is negative and significant at the 6% level.

Finally, we also examined reported U.S. and world economic gold reserves, though we were cautioned that these figures are not very reliable. Neither exhibited the negative correlation with prices over our sample period that might suggest the concavity is being driven by such a statistical artifact.

V. Where’s the Fat?

If indeed fat explains a substantial fraction of the concavity of \( S \) that we often find, what is this fat? And how do firms vary in the extent to which they are subject to such fat: for instance, might it be related to size, or to the absence of large shareholders?

Unfortunately, our ability to study such questions is quite limited, both because we have only 17 firms and, more fundamentally, because our methodology yields bounds, not estimates, for fat. While we find statistically and economically significant variations in the

\(^{45}\) More precisely, we used the firm’s reported economic reserves for the year in which the observation occurs. Conversations with industry participants, however, did not encourage us to put a lot of faith in these firm-level reports.
curvature of different firms’ $S$ functions, since we do not observe $V$ we cannot confidently infer anything about variations in the fat functions; we would expect different firms to have markedly differently curved $V$ functions. To illustrate, suppose that firm A owns a single mine with extraction costs of $50 per ounce for all gold in the mine, while firm B owns a portfolio of mines with an array of extraction costs from $10 to $1000 per ounce. Then firm A would have a virtually linear $V$ function, while B’s would be quite convex.

Nonetheless, a natural response to our findings is to ask wherein this fat consists, and what determines how much of it there is. We asked these questions in our interviews with industry executives. Below, we discuss two places we have looked for fat and for factors affecting the extent of fat.

A. Exploration Costs.

All the managers we spoke with seemed to believe that — either as an obviously sound business policy, or because of pressure from stock-market analysts — a gold-mining firm should “replace” its extraction, whether by exploration for new reserves or by acquisition of existing mines (or of mine-owning companies). Several suggested that when gold prices are high, firms found themselves “having to” and/or “able to” undertake quite unpromising exploration projects.

Because it is much harder to verify whether an exploration decision is value-increasing than whether a mine is being well managed, exploration seems a likely locus for potentially value-reducing expenditures. In related work in the oil industry (Borenstein and Farrell, 1996), oil industry commentators told us that the industry dissipated much of the value increase during the early 1980s by “excessive” (at least ex post) exploration. Clearly, a price increase should induce some increase in exploration, but these observers suggested that the oil industry’s response was excessive.46

In gold mining, a rule of thumb that firms must replace extraction would suggest one simple principal-agent theory for value dissipation after gold price increases. Suppose that

46 Jensen (1986) presents evidence of value-reducing exploration in the oil industry.
mines are run as profit centers, or more broadly that mine managers have incentives to increase output when \( p_g \) rises, in a way that takes account of increased extraction costs but does not take account of the marginal cost of finding more gold. Then their output-increasing decisions, while optimal if the firm optimized overall, could actually reduce the firm’s value if the firm forced itself to follow the rule of thumb that it must replace all extraction.

Another possible theory, attributing the anomaly to the financial markets rather than to a principal-agent problem inside the firm, would be that some firms resist this rule of thumb and are penalized by stock-market analysts who look for growth or at least sustainability of revenue. Several executives told us that they believe analysts behave in this way.

**B. Non-Optimal Labor Compensation.**

As mentioned earlier, if labor takes an increasing fraction of firm wealth as wealth grows, it could account for concavity of the net (i.e., stock market) value function. To the extent that this goes beyond an optimal ex ante contract and becomes an inefficient ex post holdup or asset-stripping, one might call it fat. Though it can be hard to distinguish efficient from inefficient variations in labor compensation, it seems unlikely to be efficient to reward miners for changes in firm value driven by exogenous changes in the price of gold. But, while such labor rent-sharing has been documented in some industries,\(^{47}\) our discussions with industry participants suggested that it is not likely to be much of an issue in gold mining. None reported that wages moved noticeably with the price of gold.

**VI. Conclusion**

Once one recognizes that firms could be inefficient, one might suspect that they get fatter as their wealth grows. In the gold mining industry, we found empirically that an increase in gold prices increases many firms’ stock-market values by more when the price

\(^{47}\) See, for instance, Rose (1987).
of gold is low than when it is already high. This empirical concavity contradicts the basic theoretical prediction of convexity driven by the upper-envelope, or real option, effect for an optimizing firm.

The concavity result is particularly striking in that real options are important in gold mining firms’ business decision making. As Moel and Tufano (2002) documented, firms open and close mines in response to changes in the price of gold. Such flexibility in production plans should, following standard theory, make a firm’s value strongly convex as a function of the price of gold. We find that for more than half of the gold mining firms we study, it does not.

We posit that much of the observed concavity reflects investors’ beliefs that at least some firms will dissipate a share of wealth gains and that this share will be larger when the firm is wealthy. We discuss a number of alternative explanations for concavity and conclude that they do not credibly explain our findings.

Our methodology used the fact that gold mining is close to a price-taking industry; thus variation in market power is not the source of variations in firm wealth in our study. But market power can also be a source of firm wealth. Our results are consistent with the popular view that monopoly fat may dissipate what would otherwise be monopoly profits, increasing (perhaps dramatically) the deadweight loss of monopoly. If that is true, encouraging competition may improve productive as well as allocative efficiency.

</tbody>
</table>

* change in slope from bottom to top quartile.

$^+$ indicates statistically significant convexity (at 5% level) when comparing slope in top and bottom quartile.

$^-$ indicates statistically significant concavity (at 5% level) when comparing slope in top and bottom quartile.

GLS with correction for heteroskedasticity caused by $S_{it-1}$ in residual (equation [18]).

White standard errors in Parentheses.
