Abstract

This research reports an investigation of the influence of the mechanically induced martensitic transformation on the fatigue crack growth rate in 304-type austenitic stainless steels. The steels 304L and 304LN were used to test the influence of composition, the testing temperatures 298 K and 77K were used to study the influence of test temperature, and various load ratios were used to determine the influence of the mean stress. It was found that decreasing the mechanical stability of the austenite by changing composition or lowering temperature reduces the fatigue crack growth rate and increases the threshold stress intensity for crack growth. However this beneficial effect diminishes as the load ratio increases, even though increasing the load ratio increases the martensite transformation. Several mechanisms that may affect this phenomenon are discussed, including the perturbation of the crack-tip stress field, crack deflection, and the work hardening characteristics and relative brittleness of the transformed material. The perturbation of the stress field seems the most important; by modifying previous models we develop a quantitative analysis of the crack growth rate that provides a reasonable fit to the experimental results.

I. INTRODUCTION

Many common austenitic stainless steels are mechanically metastable at low temperature and spontaneously transform into the martensite phase when subjected to sufficient stress or strain. The martensitic transformation causes a shape deformation that is evidenced by surface-relief effects [1] and a volume change that is dependent on the composition and is \( \alpha + 2\% \) in 304-type stainless steels [2,3]. During fatigue crack growth the transformation is induced in the strain field ahead of the crack tip. The strain accompanying the transformation alters both the microstructure and the stress state at the crack tip, and should, therefore, change the fatigue crack growth rate. It is necessary to understand these changes to design reliable engineering structures and to design or select structural steels with suitable fatigue resistance.

While there have been many research studies on the influence of the mechanically induced martensitic transformation on tensile properties, there is relatively little prior work on fatigue crack propagation in metastable austenitic steels. The bulk of the relevant work [4-12] suggests that the martensitic transformation decreases the crack growth rate. Excepting reference [11], however, the fatigue crack growth measurements were confined to the Paris, or power-law region of crack growth. The microstructural mechanism of the transformation effect is not understood. The present work was undertaken to clarify the mechanisms of fatigue crack propagation in metastable austenitic steel. It involved a study
of fatigue crack growth in both the Paris and near-threshold regions in 304-type stainless steel as a function of composition, temperature and load ratio.

II. EXPERIMENTAL PROCEDURE

Materials

The materials used in this study were commercial grade AISI 304L and 304LN stainless steels. Their chemical compositions are listed in Table I. They differ primarily in nitrogen content, which is higher in 304LN. Increasing nitrogen raises the yield strength at low temperature (Table II) and stabilizes the austenite phase. 304L plates were processed in two different ways. The basic material was annealed at 1050 °C for 1 hour followed by a water quench to create a homogeneous austenite phase. Some of these plates were then rolled 13% at liquid nitrogen temperature to form a two-phase mixture of austenite and martensite. 304LN was used in the as-received (annealed and quenched) condition. The average grain sizes of 304L and 304LN were 100 µm and 70 µm, respectively. Optical micrographs of the annealed 304L and cold-rolled 304L are shown in Fig. 1. X-ray diffraction tests confirmed that the annealed 304L and as-received 304LN were essentially pure austenite (γ), while the cold-rolled 304L was about 50% austenite, 50% martensite (α') with a small admixture of the hexagonal, ε-martensite phase. The tensile properties of the annealed and as-received 304LN were measured and are listed in Table II.[12]

The martensite start temperatures on cooling (Ms) and deformation (Md) were estimated from the empirical formulae given in references [13,14], and are: for 304LN, Ms < 0 K, Md < 255 K; for 304L, Ms < 38 K, Md < 299 K. The thermal stability of the annealed 304L steel was confirmed by soaking in liquid helium for more than 2 hours; no α' or ε-hcp martensite was detected by X-ray diffraction. The volume fractions of martensite as a function of tensile strain at room and liquid nitrogen temperatures were measured by x-ray diffraction.[12] The results were plotted in Fig. 2. Despite the similarity of the computed Md temperatures, the austenite phase in 304L is very much less stable on mechanical deformation than that in 304LN.

Fatigue Crack Propagation

The fatigue crack propagation tests were conducted according to the procedures recommended in references [15,16]. Fatigue crack growth rates were measured on 12.7 mm and 25.4 mm thick compact tension specimens of the geometry and size suggested by ASTM standards.[15] The fatigue crack plane lay in the L-T orientation. The specimens were tested under load control in a hydraulic testing machine with a compression tube frame, using a sine-wave load form and a frequency of 10-30 Hz. The cyclic stress intensity (ΔK) was calculated from the crack length and cyclic load as suggested by the ASTM standards.[15] The crack length was monitored continuously using the direct-current electrical potential method.[16,17] The crack length was recorded as a function of cycle number on a strip-chart recorder and the fatigue crack growth rate, da/dN, was determined from the slope of the curve. Fatigue crack growth was monitored over a range of growth rates from $10^{-11}$ to $10^{-6}$ m/cycle to sample both the near-threshold and the Paris regions. The near-threshold crack growth rates were measured under decreasing ΔK conditions (the "load shedding" method)[16,18] using a step-wise decrement in ΔK of less than 7% per step. At each load level the crack was allowed to propagate for a distance at least 3 times the computed maximum radius of the plastic zone formed at the previous load level. After establishing the threshold, the load was increased step-wise and da/dN values were recorded until the specimen sustained general yield. The room temperature (RT) fatigue tests were done in air at about 298 K; the tests at liquid nitrogen temperature (LNT: 77 K) were done by immersing the compression tube and specimen in a 25 liter dewar filled with liquid nitrogen.

The extent of crack closure during fatigue crack growth was monitored continuously using the back-face strain gauge technique.[19,20] In this technique a strain gauge is mounted on the back face of the specimen and the closure stress intensity, which represents the macroscopic contact of the fracture surfaces during unloading, is determined from the load at which the elastic compliance curve first deviates from linearity.
Optical Microscopy

The deformation-induced martensite around the fatigue crack was observed after the fatigue test by optical microscopy on samples that were sectioned perpendicular to the crack plane at center thickness. Tests showed that no martensite was induced during grinding or polishing. Two methods were used to reveal the martensite: (1) chemical etching in a solution of 15 ml HNO₃, 45 ml HCl, 20 ml methanol for about 1 minute, which reveals the grain boundaries and interfaces between martensite and austenite, and (2) painting the surface with ferrofluid,[21,22] which highlights the magnetic α' martensite in the paramagnetic austenite matrix. While all of the optical metallography was done at room temperature, there was no evidence of martensite reversion during heating from 77 K and none is believed to occur.[23]

X-ray Diffraction and Scanning Electron Microscopy

The fatigue fracture surfaces of the specimens were studied under a scanning electron microscope. The γ, α' and ε phase fractions in the material near the fracture surface were measured by x-ray diffraction. The relative volume fractions of the three phases were determined by comparing the integrated intensities of the (200)γ, (200)α', and (10.1)ε peaks.

III. RESULTS

Fatigue Crack Propagation

To explore the influence of the martensite transformation on the fatigue crack growth rate the extent of transformation during fatigue was varied in three different ways: (1) by changing the chemical composition from that of 304L to that of 304LN, (2) by lowering the temperature from room temperature to liquid nitrogen temperature, and (3) by varying the load ratio. The consequences of these three changes are the following.

Chemical Composition. The measured crack growth rates of 304L and 304LN at 298 K and 77 K for the load ratio R = 0.05 are plotted in Figs. 3(a) and 3(b) respectively. The fatigue crack growth rates of the two alloys are very nearly the same at room temperature. However, at 77 K the crack growth rate of 304L is 10 times slower than that of 304LN at ΔK = 10 MPa√m, and is 4 times slower at ΔK = 50 MPa√m. These results correlate directly with the extent of martensitic transformation in the two alloys. Metallographic studies of the fatigue crack profiles show that at room temperature both 304L and 304LN remain essentially austenitic at the crack tip as ΔK is varied from 3 to 40 MPa√m. Hence the fatigue crack growth rate at room temperature is not significantly affected by martensitic transformation in either alloy. The fatigue crack growth rates are similar despite differences in the static mechanical properties of the two alloys (Table II). At 77 K, on the other hand, 304L is substantially transformed while 304LN is only transformed slightly at the higher values of ΔK. As shown in Fig. 4(a), very little martensite appears near a fatigue crack in 304LN that grows at ΔK values as high as 15 MPa√m.
However, as shown in Fig. 4(b), martensite coats a growing crack in 304L even when $\Delta K$ approaches $\Delta K_{th}$, and a broad region of extensive transformation is present when $\Delta K$ is greater than about 20 MPa$\sqrt{m}$. The fatigue crack growth rate decreases significantly when the chemical composition is changed to promote deformation-induced martensite.

The fatigue crack growth rates of 304L and 304LN at 77 K at a higher load ratio (R = 0.5) are compared in Fig. 3(c). The crack growth rate is, again, significantly slower in 304L. The decrease is less at R = 0.5 than at R = 0.05 (compare Figs. 3(c) and 3(a)). However, the difference in the degree of martensitic transformation is greater. Increasing the load ratio from R = 0.05 to R = 0.5 for given $\Delta K$ results in a larger transformation zone with denser martensite in 304L (Fig. 9(a)), while about same degree of transformation occurs in 304LN.

**Temperature.** Fig. 3(d) illustrates the effect of decreasing the test temperature on the fatigue crack growth rate in the two metastable steels. The fatigue crack growth rate of 304L at room temperature, where the austenite phase is stable, is significantly greater than that at liquid nitrogen temperature, where the alloy undergoes extensive transformation. On the other hand, Fig. 3(e) shows that the fatigue crack growth rate in 304LN is relatively insensitive to temperature at lower $\Delta K$ values where the transformation is insignificant at both test temperatures. Again, the martensitic transformation reduces the fatigue crack growth rate.

**Load ratio.** The influence of the load ratio on the fatigue crack growth rate at 77 K is illustrated in Figs. 3(f) and 3(g). The plot shows that as the load ratio, R, increases from 0.05 to 0.5 (representing a 1.9 times increase in $K_{max}$ for given $\Delta K$), the fatigue crack growth rate curve shifts sharply to the left for the unstable alloy, 304L, but is essentially unchanged for 304LN except at very high $\Delta K$ where some transformation occurs. This result is in agreement with prior work\[12\] which measured an increase in the fatigue crack growth rate of 304L by a factor of 18 as R increased from 0.1 to 0.75 at 77 K.

An increase in the fatigue crack growth rate with the load ratio is a common phenomenon, but the effect is usually small. Fig. 5 contains a plot of data drawn from the literature on the fatigue crack growth rates of austenitic steels. The fatigue crack growth rate at given R is normalized by dividing it by the growth rate at R = 0.1; the value is approximately same for all $\Delta K$ in the linear, Paris-law region of the crack growth curve. In all cases the fatigue crack growth rate increases with R, but by an amount that is significantly greater under conditions where the austenite is relatively unstable. These results suggest that the martensitic transformation exaggerates the load-ratio effect.

The abnormally large R-ratio effect in metastable austenitic steels is surprising since the extent of the martensitic transformation increases with R at given $\Delta K$. The composition and temperature results suggest that the crack growth rate should decrease with the extent of the martensite transformation. Taken together the results suggest that the reduction in the crack growth rate due to the transformation depends on the load ratio, that is, high tensile mean stress lessens and even eliminates the effect of the transformation. Fig. 6 includes all the crack growth rate data taken in research to date. It shows that as the R-ratio
increases the crack growth rate of 304L at 77 K approaches that of 304LN and that of 304L at room temperature where the alloy is stable.

**Crack Closure**

Crack closure during the fatigue cycle was measured using the back-face strain gauge technique described above. The results are plotted in Fig. 7. Crack closure was only observed in the near-threshold region, and only when the alloy transformed extensively at the crack tip. Closure occurred in the near-threshold region of both annealed and cold-rolled 304L at liquid nitrogen temperature, but was not observed for annealed or cold-rolled 304L at room temperature or for 304LN at either temperature. The results indicate that the martensite transformation on the mating surfaces induces crack closure near the threshold, as discussed by Suresh and Ritchie.[28] On the other hand, the data suggest that transformation-induced crack closure is not the cause of decreased fatigue crack growth rates at higher ΔK.

**Martensite Transformation around the Fatigue Crack**

There are two possible martensitic transformation products in the Fe-Ni-Cr alloy system: the α' (bcc or bct) and ε (hcp) phases. The γ→α' transformation involves a 2% volume expansion, while the γ→ε transformation occurs at nearly constant volume in 304-type alloys. Since both the γ and ε phases are paramagnetic, magnetic etching reveals only the ferromagnetic α' phase. Fig. 8 shows the distribution of α' around a fatigue crack. No evidence of ε-martensite was found in the x-ray diffraction patterns.

To compare the extent of transformation a transformation zone size was arbitrarily defined as the distance from the crack surface at which a 10% martensite transformation occurred. The measurements were made on etched cross-sections, and are hence somewhat imprecise, but do show consistent trends. The data for annealed 304L tested at liquid nitrogen temperature are plotted in Figs. 9(a) and 9(b) as functions of ΔK and K_{max}, respectively. Since the transformation is driven by the strain, which varies roughly as K/\sqrt{R} near the crack tip, we had expected that the transformation zone size, δ, would be proportional to K_{max}. Fig. 9(b) shows that this is not the case. Nor is δ a unique function of ΔK. However, the curves in Fig. 9(a) are well fit by an expression of the form

\[ \delta = A(\Delta K - C)^2 \]  

where A and C are constants whose values change with R (or, equivalently, with K_{max}). Equation (1) implies that there is a threshold value of the cyclic stress intensity for the transformation.

**Fractography**

The fatigue crack is transgranular for all conditions studied, as illustrated by the fatigue crack profiles in Figs. 4(a,b). The fatigue fracture surfaces of 304L (Fig. 10(a)) and 304LN (Fig. 10(b)) tested at 298 K suggest that significant plastic deformation occurs
during fracture. On the other hand, the fatigue surfaces of 304LN (Fig. 10(c)) and 304L (Fig. 10(d)) tested at LNT contain flat features that resemble quasi-cleavage. The ridges that represent plastic deformation start from the grain boundaries in Fig. 10(d), while the anneal twin boundaries in Fig. 10(e) do not interrupt the ridges. Recalling the shape of the mechanically induced α' shown in Figs. 4(a)-(d), α' features can be identified on the fatigue surfaces in Figs. 10(c and d). Fig. 10 shows the form of α' on the fatigue surface of 304L tested at high ΔK and high load ratio where extensive transformation occurs. It is interesting to notice that the α' on the surface appears as if it were deformed in compression, which suggests the possibility of a microscopic crack closure that is not detected by the back-face strain gage technique.

IV. DISCUSSION

Fig. 6 includes all the fatigue crack propagation test data. Two conclusions can be drawn. First, the deformation induced martensitic transformation increases fatigue resistance. The threshold stress intensity increases and the fatigue crack growth rate decreases for all ΔK. Second, the beneficial effect of the transformation decreases as the load ratio increases.

A number of mechanisms have been proposed that may contribute to the influence of the martensite transformation on the crack growth. These include the effect of the volume or shear strain associated with the transformation at the crack tip, the influence of the transformation and the resulting dual-phase microstructure on the crack path, the influence of the transformation on the aggregate mechanical properties of the material at the crack tip, and the influence of the transformation on the fracture mode. We discuss the available models that represent these effects in turn. Among these mechanisms, the effect of the transformation strain appears to be the most important.

A. Influence of the Martensite Transformation on the Crack Tip Stress Field

The most obvious mechanism that influences crack growth in metastable austenitic steels is the perturbation of the crack tip stress field by the strain associated with the transformation. The γ→α' transformation in 304-type steels involves both a ~2% volume expansion and a ~10% shear strain. The influence of the volume expansion is the simpler to treat, and is analyzed in recent works by McMeeking and Evans, Budiansky, et al. The influence of the shear component is much more difficult to analyze. The beginnings of a quantitative analysis appears in recent work by Lambropoulos.
compressive stress does not change the amplitude of the tensile cycle because both $P_{\text{max}}$ and $P_{\text{min}}$ are reduced by the same amount, but the load ratio changes from $(P_{\text{min}} / P_{\text{max}})$ to $(\Delta \text{P}_{\text{max}} / \Delta P_{\text{min}})$, where $\Delta$ is the reduction of the tension load by the compressive stress. If $P_{\text{min}}$ is a small positive number, it may be reduced to a negative value, the amplitude of the tensile cycle is then $(P_{\text{max}} - \Delta)$, and the load ratio is zero. Since the crack growth rate depends primarily on the amplitude of the tensile cycle and secondarily on the load ratio, the reduction of the amplitude and load ratio by the compressive stress slows the rate of crack propagation. This effect is qualitatively capable of explaining the influence of the transformation on the crack growth rate: the compressive stress reduces the crack growth rate, but the effect is less pronounced as the load ratio increases since a higher means a higher value of $P_{\text{min}}$ and a smaller effect on the amplitude of the tensile cycle.

The influence of the volume expansion on the stress field and stress intensity factor are analyzed below in an attempt to quantify its influence on the fatigue crack growth rate. To do this we must modify previous analyses of the effect.[30,31]

The Stress Field. Let a dilatant cylindrical martensite particle be inserted into an infinitely large elastic body. The stress field outside the cylinder can be calculated by modifying the Lamé solution for a thick-walled tube subjected to a internal pressure,[33]

$$
\sigma_{rr} = -P \frac{(R_0/r)^2 - 1}{(R_0/R_1)^2 - 1}, \quad \sigma_{\theta\theta} = P \frac{(R_0/r)^2 + 1}{(R_0/R_1)^2 - 1}, \quad \sigma_{r\theta} = 0
$$

If we let $R_0 / R_1$ (the ratio of the outside radius to the inside radius) tend to infinity and use L' Hospital's rule, then the two-dimensional stress field outside the particle is

$$
\sigma_{rr} = -P \left[ \frac{R_1}{r} \right]^2, \quad \sigma_{\theta\theta} = P \left[ \frac{R_1}{r} \right]^2
$$

The stress field inside the cylinder is constant and hydrostatic

$$
\sigma_{rr} = \sigma_{\theta\theta} = -P = -\alpha B e^T
$$

where $e^T$ is the volumetric strain of the martensitic transformation, $B$ is the bulk elastic modulus of the martensitic particle, and $\alpha$ is a parameter, $0 \leq \alpha \leq 1$, whose value depends on the relative stiffness of the particle and the matrix. If the matrix is much more stiffer than the martensite particle, $\alpha = 1$, in the other extreme, $\alpha = 0$.

If such a cylindrical martensite particle forms directly in front of a growing crack the driving force for the crack extension is the opening stress, $\sigma_{\theta\theta}$. It follows from equation (3) that as the crack approaches the particle it is subject to a tensile stress that varies as $r^{-2}$ and adds to the cyclic stress at the crack tip due to the macroscopic load. The crack does not experience the compressive field of the martensite transformation until it actually penetrates the particle.
The Stress Intensity Factor. The stress field at the tip of a crack in a body under an external tensile load is characterized by the mode I stress intensity factor, $K_1$. The transformation stress, $\sigma_{\theta\theta}$, changes $K_1$. The amount of the change, $\Delta K_1$, can be found by calculating the stress intensity factor due to $\sigma_{\theta\theta}$ alone and applying the superposition principle. Given the stress field, $\sigma_{\theta\theta}(r,\theta)$, $\Delta K_1$ can be found, as proposed in ref. [34], by evaluating an integral of the $K_1$ solution for a pair of concentrated splitting forces on the crack surface. However, the shape of the transformed zone in front of the crack is not simple, and the stress field is difficult to find.

An alternative method for finding $\Delta K_1$ was recently proposed by McMeeking and Evans,[30] who used the Eshelby cycle[35] to find the transformation stress and employed a weight function method[34,36] to evaluate the change in stress intensity. In the Eshelby method the stress and strain fields introduced by a dilatation of magnitude, $\varepsilon^T$, are calculated by summing the fields introduced in a sequence of steps that lead to the final state of the elastic inclusion. A region of the material is cut out and removed from the matrix, then given a volumetric strain, $\varepsilon^T$. This strain is reversed by imposing a surface traction, $T_c(r,\theta) = -n(r,\theta)\varepsilon^T$, where $C$ is the elastic matrix of the martensite product and $n(r,\theta)$ is the outward surface normal. The transformed material is then put back to the matrix and rewelded. Since the material inside transformed region is under the stress, $-\varepsilon^T$, it relaxes against the unstressed matrix. The relaxation is accomplished by applying a traction $T(r,\theta)$ to the boundary of the particle, since the interface has no traction in its final state. The stress intensity factor generated by the transformation is, hence, equivalent to that generated by a traction, $T(r,\theta)$, on the boundary of the transformed region. Using the weight function method, the stress intensity factor can be calculated by evaluating the line integral of the scalar product of $T(r,\theta)$ and the vectorial weight function $h(r,\theta)$ along the transformed region boundary, $S$,

$$\Delta K_1 = \int_S T(r,\theta) \cdot h(r,\theta) \, dl$$

The weight function, $h(r,\theta)$, is a measure of the contribution of a unit traction at $(r,\theta)$ to the stress intensity factor of an elastic crack.

If the $\gamma\rightarrow\alpha'$ transformation is a pure volume expansion, $T(r,\theta)$ is equal to $[n(r,\theta)B\varepsilon^T]$. The solution of $h(r,\theta)$ for a two dimensional infinite solid with a half plane crack was provided in ref. [36],

$$h_x = \frac{1}{2\sqrt{2\pi}(1-v)}\cos\left[\frac{\theta}{2}(2v+1+\sin^2\frac{\theta}{2}\cos\frac{3\theta}{2})\right]$$

$$h_y = \frac{1}{2\sqrt{2\pi}(1-v)}\sin\left[\frac{\theta}{2}(2v+1+\sin^2\frac{\theta}{2}\cos\frac{3\theta}{2})\right]$$
where \( v \) is Poisson's ratio. The boundary \( S \) varies as the crack extends since fresh material is transformed in the propagating crack tip stress field. Evans and McMeeking assumed that the transformation is driven by the hydrostatic stress, and, hence, that the boundary of the transformed zone is a contour of constant pressure:

\[
r = \frac{8w}{3\sqrt{3} \cos^2\frac{\theta}{2}}
\]

where \( w \) is a measure of the width of the contour, taken to be one-half the zone width. Their result for \( \Delta K_1 \) is plotted along with the computed zone shape in Fig. 11; the stress intensity factor is reduced by an amount, \( -\Delta K_1 \), that is zero prior to crack extension, then increases and saturates as the crack enters into the zone. Its asymptotic value is

\[
\Delta K_1 = -0.22 \left[ \frac{E}{1-v} \right] V_f \sqrt{w e^T} = -0.33 P \sqrt{w}
\]

where \( V_f \) is the fraction of martensite in the zone, \( E \) is Young's modulus, \( v \) is Poisson's ratio (approximated as \( 1/3 \)), and \( P \) is the transformation pressure, equal to \( BV_f e^T \), where \( B \) is the bulk modulus.

While equation (9) has apparently been used with some success to treat transformation toughening in ceramics, specific calculation shows that the magnitude of \( \Delta K_1 \) is too small to account for the effects observed in the present work. We therefore modified the Evans-McMeeking solution in two respects that are indicated by the detailed state of the material at the growing crack tip.

1. **Zone Shape.** The martensite zone shape assumed by Evans and McMeeking is determined by a contour of constant hydrostatic stress. However, the \( \gamma \rightarrow \alpha' \) transformation in 304 stainless steels involves a greater shear strain (~10% [29]) than volume expansion (~2% [2,3]) and should hence be more strongly affected by the local shear stress. This is true even when the overall transformation stress is nearly hydrostatic; the formation of a sheared martensite plate promotes the local formation of others in twinned orientation that tend to cancel the overall shear. Nonetheless it seems reasonable to assume that the initial transformation, which triggers the process, is determined more by the local shear than by the local hydrostatic stress. This phenomenon is strikingly evident in computer simulations of the stress-induced martensite transformation [37] and is consistent with observations of the martensite zone shape in this and other work [8,38] which show transformation zones that follow shear stress contours much more closely than hydrostatic stress contours.

Using the Von Mises measure of shear stress for the plane strain condition,

\[
\bar{\tau} = \sqrt{\frac{1}{2}[(\sigma_{xx} - \sigma_{yy})^2 + (\sigma_{yy} - \sigma_{zz})^2 + (\sigma_{zz} - \sigma_{xx})^2 + 6\sigma_{xy}^2]}
\]

A contour of constant equivalent shear is specified by the relation,
where \( c(v) \) is a factor that fixes the width, \( w \), of the contour. The shapes of the constant hydrostatic stress and constant equivalent stress contours are sketched in Figs. 11(a-b).

The integral (5) can be solved numerically for \( \Delta K_I \) as a function of the crack extension for a transformation zone that has the shape given by equation (11). The result is given in Fig. 11(b), and shows that a transformation governed by the equivalent shear stress is more effective in reducing the stress intensity factor than a transformation driven by the hydrostatic stress. Moreover, \( \Delta K \) is not zero at the beginning of crack growth. The asymptotic value for the plane strain condition with \( v = 1/3 \) is

\[
\Delta K_I = -0.5 \ P\sqrt{w} \tag{12}
\]

which is more than a 50% greater reduction than in the hydrostatic case.

The reason that the shear-controlled transformation is more effective in reducing the stress intensity becomes apparent when the integral (5) is re-expressed as an integral over the area, \( A \), enclosed by the contour,

\[
\Delta K_I = \int_A B \epsilon^T n(\theta) \cdot h(\theta, \theta) \, dl = \int_A B \epsilon^T v \cdot h(\theta, \theta) \, ds
\]

\[
= \int_A \frac{E \epsilon^T}{6\sqrt{2\pi(1-v)}} r^{3/2} \cos \left[ \frac{3\theta}{2} \right] \, ds \tag{13}
\]

The integrand in eq. (13) gives the contribution to \( \Delta K_I \) from a transformed particle located at \( (r, \theta) \). Because of the factor, \( \cos(3\theta/2) \), in the integrand, transformed particles that are located in a wedge-shaped region in front of the crack (\( -60^\circ < \theta < 60^\circ \)) increase \( \Delta K_I \), while particles located outside this region decrease it. When the transformation occurs within a contour of constant shear a much higher fraction of the transformed region lies in the zone that decreases the stress intensity than when the transformation follows a contour of constant pressure.

2. Martensite Distribution. The calculations leading to eqs. (9) and (12) assume that the transformation is homogeneous over the region in which it occurs: the transformed fraction is equal to \( V_f \) everywhere inside the transformed zone, and is zero outside. In reality the fraction transformed varies continuously with distance from the crack surface; as shown in Fig. 4, for example, the fraction of martensite is high at the crack surface and decreases significantly with distance. It is evident from equation (13) that the inhomogeneity of the martensite distribution is important. Because of the factor \( r^{3/2} \) in the integrand a
transformed particle that is close to the crack tip has a much larger effect on the stress intensity than one that is further away.

Eq. (12) can be modified to account for the inhomogeneous martensite distribution. Assume that a zone of width \( w \) has a martensite volume fraction, \( V_i \), at the crack surface and let it decrease with distance, \( x \), according to the function, \( V(x) \), to the value, \( V_0 < V_i \), at the zone boundary. To compute the change in stress intensity we imagine that the zone is created by a sequence of elementary transformations and use the superposition principle. In this picture, the austenite inside the zone of width \( w \) transforms to the fraction \( V_0 \), then a smaller zone of width \( x_1 \) transforms further to \((V(x_1) - V_0)\), a still smaller zone of width \( x_2 \) transforms further to create the volume fraction \((V(x_2) - V(x_1))\), and so on until the whole inhomogeneous transformation is taken into account. The value of \( \Delta K_1 \) in each step can be calculated by (9) or (12), and the total change is given by the integral,

\[
\Delta K_1 = -C\sqrt{w}V_0 + \int_0^w C\sqrt{x} \frac{dV(x)}{dx} \, dx
\]

where \( C = KB\varepsilon_T \), and \( K = 0.33 \) if eq. (9) is used and \( K = 0.5 \) if eq. (12) is used. If a linear distribution is assumed,

\[
V(x) = V_0 + (V_i - V_0) \left[ \frac{w-x}{w} \right]
\]

and (13) becomes,

\[
\Delta K_1 = -C\sqrt{w}V_0 - \int_0^w C\sqrt{x} \frac{V_i - V_0}{w} \, dx
\]

\[
= -C\sqrt{w}V_0 - \frac{2}{3} C\sqrt{w}(V_i - V_0)
\]

The value of \( V_0 \) is the martensite fraction at the transformation zone boundary and is about 10% by optical microscopy measurements, while the value of \( V_i \) is the martensite fraction at the crack surface and is about 50% by X-ray diffraction measurements. This effect can be significant. For the conditions stated \( \Delta K_1 \) is about 25% larger than the value calculated on the assumption that the volume fraction is homogeneous and equal to its average value.

Given the assumption of a shear-controlled transformation and a linear transformation profile, \( \Delta K_1 \) can be calculated if the transformation zone width, \( w \), is known. In the present work we found the zone width experimentally for 304L at 77 K for three values of the load ratio. The results are plotted as a function of \( \Delta K \) in Fig. 9. After the fatigue tests, transformation zone sizes were measured by optical microscope as a function of \( \Delta K \) (Fig.
It was found that the three sets of data in Fig. 9(a) could be fit by an relation of the form

\[ w = A(\Delta K - C)^2 \]  

(17)

where the values of A and C depend on the load ratio, R. Substituting this result into eq. (16) yields \( \Delta K_I \) as a function of \( \Delta K \). The resulting values of \( \Delta K_I \) are plotted in Fig. 12 along with the values of \( K_{\max} \) and \( K_{\min} \).

As shown in Fig. 12 the magnitude of \( \Delta K_I \) increases with \( \Delta K \), essentially because a higher \( \Delta K \) causes a more extensive transformation. On the other hand, the stress intensity at crack closure, \( K_c \), that is measured by the back-face strain gage is nearly independent of \( \Delta K \). These results are superficially inconsistent since the crack should close at its tip when \( K = |\Delta K_I| \), but closure is not observed until the stress intensity reaches the value \( K = K_c \), which is greater than \( |\Delta K_I| \) when \( \Delta K \) is near the threshold, but is much smaller at larger values of \( \Delta K \). It does not seem reasonable that the discrepancy is simply due to the approximations in the calculation of \( |\Delta K_I| \); however the transformation effect is calculated the increased martensite fraction should lead to a higher value of \( |\Delta K_I| \) and hence to earlier crack tip stress relaxation at higher \( \Delta K \). We suspect that the discrepancy (and the relatively constant value of \( K_c \)) is due to the back-face strain gage measures a qualitatively different phenomenon: the macroscopic closure of the crack over a length sufficient to produce a measurable increase in the modulus. The effect of \( \Delta K_I \), on the other hand, is local and specific to the crack tip itself; when \( K = |\Delta K_I| \) only the very tip of the crack is relaxed. The macroscopic closure, \( K_c \), reflects a number of phenomena, such as the crack roughness; the transformation may not determine its value. On the other hand, the relaxation at the crack tip itself is determined by \( \Delta K_I \), and can induce closure at the crack tip, essentially removing the driving force for crack growth, even when the crack remains open in a more macroscopic sense.

From this perspective the effective cyclic stress intensity, \( \Delta K_{\text{eff}} \) is limited by the larger of three terms: the minimum stress intensity, \( K_{\min} \), the stress intensity for macroscopic closure, \( K_c \), and the transformation stress intensity, \( |\Delta K_I| \). If \( K_{\min} \) is the largest of the three the crack never closes. If \( K_c \) is the largest the lips of the crack touch, possibly at a position slightly away from the crack tip, and relax the crack-tip stress concentration. If \( |\Delta K_I| \) is the largest the stress intensity is relaxed locally at the crack tip. The cyclic stress intensity that should be used in the crack growth law is, then,

\[ \Delta K_{\text{eff}} = K_{\max} - \max\{K_{\min}, K_c, |\Delta K_I|\} \]  

(18)

To test this hypothesis the fatigue crack growth curves given in Fig. 9(f) are re-plotted to show the fatigue crack growth rate as a function of the effective stress intensity \( (\Delta K_{\text{eff}}) \) in Fig. 13. While the curves do not completely coalesce, they agree much more closely with one another. Since \( \Delta K_{\text{eff}} \) is determined by \( \Delta K_I \), whose value is known only approximately, over most of the range plotted, the agreement seems reasonably good.
Shear Strain

The calculation that is made above considers only the volume expansion term in the martensite transformation strain. The shear strain in the transformation should also reduce the stress intensity at the crack tip. Unfortunately, this effect is very difficult to estimate quantitatively. The formation of a martensite particle in a particular variant tends to trigger the formation of adjacent particles in variants with compensating shears. Only the net shear affects the overall strain field. The beginnings of an analysis of this effect were made by Lambropoulos[32], who assumed that the locations and factions of the different variants of martensite adjust to eliminate the deviatoric component of the macroscopic stress. He was then able to estimate a net value for the transformation strain from this assumption with the additional approximation that the martensite particles are ellipsoidal, so that Eshelby's solution for the elastic field[35] could to be employed. The validity of the assumptions is not at all clear, and the results of the calculation for $\Delta K_I$ is very sensitive to the assumed orientation of the martensite particles. However, he concludes that the effect of the shear can be large; $\Delta K_I$ due to the shear strain can be double that due to volume expansion alone.

Since the particle orientation in our fatigue experiments was not regular, it is not clear how to apply his results to our case, and we did not attempt to do so. Nonetheless we are continuing to investigate the influence of the shear strain.

B. Other Mechanisms

Metallurgical effects besides the perturbation of the crack-tip stress may also influence fatigue crack growth in a material that undergoes transformation. The following were specifically investigated.

Dual-phase Microstructure

The transformation at the crack tip creates a $\gamma + \alpha'$ dual-phase medium, and therefore changes the inherent crack-growth resistance of the material ahead of the crack tip. To test this effect a $\gamma + \alpha'$ structure (Fig. 1 (b)) was produced artificially by cold-rolling and tested in fatigue. The results are compared with those for annealed 304L and 304LN in Fig. 14. The extent of additional transformation was monitored; it is negligible at room temperature and small at 77 K. The results of crack closure measurements for the dual-phase specimen are shown in Fig. 7.

The dual phase specimen exhibits a fatigue crack growth rate in the Paris region that is close to that in stable austenite, in agreement with previous results that suggest that crack growth rates in the Paris region are relatively insensitive to the microstructure.[39,40] The threshold behavior is affected, as is expected from the change in the stress intensity for crack closure. The fatigue crack growth rate in the dual-phase microstructure is greater than that in metastable ($\gamma$) 304L at 77 K, which provides further evidence that the decreased crack growth rate in 304L at 77 K is specifically due to the concurrent martensite transformation.
Crack Deflection

As shown in Fig. 15, the crack tends to extend between the martensite laths when material in front of it has transformed extensively. This tendency produces a wavy, zigzag crack path. It has been established in the literature that a crack under a $K_I$ loading advances with a slower speed along a zigzag path than along a flat path. This is because (a) the crack moves through a longer distance along a zigzag path than along a flat path for the same projected length; (b) the externally applied tensile opening loading ($K_I$) changes to the tensile opening plus sliding loading ($k_1 + k_2$) near the crack tip if the crack deviates from the direction normal to the loading axis. The two effects can be evaluated quantitatively on the basis of the model given in ref. [41].

Let $da/dN$ and $(da/dN)_1$ represent the respective crack growth rates with an without deflection, and let $\phi$ denote the angle of deflection from the normal direction to the loading axis. The reduction of crack growth rate due to effect (a) is given in ref. [41] as

$$\frac{da}{dn} = \cos \phi \left[ \frac{da}{dn} \right]_1, \tag{19}$$

The local stress intensities, $k_1$ and $k_2$, of a deflected crack can be expressed as functions of the mode I and II stress intensities due to the external load, $K_I$ and $K_{II}$:[42,43]

$$k_1 = a_{11}(\phi) K_I + a_{12}(\phi) K_{II}$$

$$k_2 = a_{21}(\phi) K_I + a_{22}(\phi) K_{II} \tag{20}$$

The first order solutions for the $a_{ij}(\phi)$[44] are very close to the exact solutions,[43] and are,

$$a_{11}(\phi) = \cos^3(\phi/2) \quad a_{12}(\phi) = -3 \sin(\phi/2) \cos^2(\phi/2)$$

$$a_{21}(\phi) = \sin(\phi/2) \cos^2(\phi/2) \quad a_{22}(\phi) = \cos(\phi/2) [1 - 3 \sin^2(\phi/2)]. \tag{21}$$

When $K_{II}$ is zero, as it is in the case of interest to us, eq. (20) become

$$k_1 = \cos^3(\phi/2) K_I, \quad k_2 = \sin(\phi/2) \cos^2(\phi/2) K_I \tag{22}$$

According to the coplanar strain energy release rate theory,[45] the effective driving force for the crack propagation is,

$$k_{eff} = (k_1^2 + k_2^2)^{1/2}$$

$$= [\cos^6(\phi/2) + \sin^2(\phi/2) \cos^4(\phi/2)]^{1/2} K_I \tag{23}$$
The maximum value of $\phi$ measured in these tests was about $30^\circ$, the minimum $k_{eff}$ calculated from (23) is 0.933 $K_I$. It is easy to see that in the case of cyclic loading, $\Delta k_{eff} = 0.933 \Delta K_I$. Plugging $\Delta k_{eff}$ into the Paris-law equation, we have

$$\frac{da}{dn} = A (\Delta k_{eff})^n = A(0.933)^n(\Delta K)^n$$

(24)

For 304L steel, $n$ is roughly equal to 3.7. Therefore, the growth rate of a deflected crack is $0.77 (= 0.933^{3.7})$ times that of a linear crack. If eq. (19) is also taken into consideration, the crack grows in its irregular path at a rate about 0.67 times that of its growth along a linear path.

While crack deflection certainly affects the crack growth rate in this case, the effect cannot be the major source of the reduced crack growth. Crack deflection reduces the growth rate, at most, $1.5 (= 1/0.67)$ times, while the experimental data (Fig. 3) indicates that the growth rate is reduced by at least a factor of 4 as a result of the transformation. Moreover, the crack propagates through the martensite particles when the transformation in front of it is not extensive. Therefore, the crack deflection effect only applies when $\Delta K$ is large.

Work Hardening

The $\gamma \rightarrow \alpha'$ transformation increases the effective rate of work hardening. This effect is apparent in Table II, which includes the ratios of the ultimate and yield strengths. Pineau and Pelloux[4] proposed that an increase in work hardening rate due to transformation would cause a reduction in the crack growth rate. However, there is no well-developed model that permits us to quantify the effect.

As reviewed by McEvily[46] the proposed mechanisms of fatigue crack propagation in the Paris region can be divided into two sets. One set focuses on the plastic sliding-off process at the crack tip, the other emphasizes damage accumulation. In the first type of model the crack growth rate can be related to the crack tip opening displacement (CTOD),

$$\frac{da}{dN} = 0.5(CTOD) = 0.5 \left[ \frac{\Delta K^2}{E\sigma_y} \right]$$

(25)

where $\sigma_y$ and $E$ are the yield stress and Young's modulus, respectively. In the damage-accumulation model a fatigue crack grows an incremental length $\Delta a$ if a critical value of the accumulated plastic displacement is reached, and

$$\frac{da}{dN} = C \left[ \frac{\Delta K^4}{E\sigma_y^3D_c} \right]$$

(26)
where $D_c$ is the critical plastic displacement. Neither of these relations is experimentally verified. However, both imply that an increase in flow stress causes a reduction in the crack growth rate.

The stress and strain fields at a crack tip in a material that exhibits power law hardening ($\sigma = A \varepsilon^n$) under $K_I$ loading have been found,\cite{47,48} and are

$$\sigma_{ij} = \left(\frac{1}{r}\right)^{n/(1+n)} \Sigma_{ij}$$

$$\varepsilon_{ij} = \left(\frac{1}{r}\right)^{1/(1+n)} E_{ij}, \quad (27)$$

where the matrices $\Sigma_{ij}$ and $E_{ij}$ are found numerically from the external loading, the work hardening coefficient, $n$, the crack orientation orientation, and the elastic constants.\cite{49} Work hardening elevates the stress at the crack tip and raises the ratio of the maximum normal stress to equivalent stress.\cite{47} At the same time, work hardening makes the strain at the crack tip more uniform. For example, in a perfectly plastic material the strains vary as $r^{-1}$, while in a hardenable material the strains vary as $r^{-1/(1+n)}$, where $0 < n < 1$. The plastic zone size decreases as $(n)$ increases.$^{[47]}$

These analyses suggest that the crack growth rate may vary in either direction with increasing work hardening. Work hardening reduces the CTOD and the plastic zone size, which should decrease the crack growth rate; on the other hand, it enhances the stresses and the normal-to-shear stress ratio, which increases the probability of fracture by cleavage. The net effect is not clear.

**Fracture Mode Transition**

Finally, there is an evident transition in the local mode of fracture when transformation intrudes in the samples studied here. The fatigue fracture surfaces in the samples that did not transform (Figs. 10 (a)-(b)) are rough and exhibit traces of significant plastic deformation; the surfaces of the samples that did transform (Fig. 10 (c)-(f)) are flat, and show a predominant cleavage or quasi-cleavage fracture mode. It appears that the material becomes brittle after the transformation, which is consistent with the behavior of fresh martensite, and should accelerate crack propagation. The brittleness of the fresh martensite phase may also contribute to the load ratio effect: at low load ratios the crack growth rate is held down by the compressive residual stress; at high load ratios the extensive transformation in front of crack and the high static stress promote a low-energy, brittle fracture. However, the experimental data suggests that this effect is not quantitatively large in these steels; the crack growth rate in the cold-rolled material that contains a high fraction of martensite is similar to that in annealed 304L, as shown in Fig. 14 (a).
V. CONCLUSIONS

1. The martensitic transformation that occurs at the tip of a growing fatigue crack in metastable 304-type steels significantly reduces the fatigue crack propagation rate in both the threshold and Paris regions. However, the effect decreases as the load ratio, or mean stress increases.

2. Several mechanisms apparently contribute to the decreased crack growth rate in steels that transform. The most important is the perturbation of the stress field at the crack tip. By modifying previous theories of the influence of the transformation on the crack tip stress intensity it is possible to obtain a theory that provides a reasonable quantitative fit to the experimental data. To improve this theory it is necessary to develop a good quantitative model that includes the net shear due to the martensite transformation. Other factors also contribute to the change in the crack growth rate. These include crack deflection, the increased work hardening rate, and the relative brittleness of the fresh martensite phase.
