Abstract

This paper consists of four parts. Part one deals with an investigation of the properties of beta-equilibrated, electrically charge neutral quark-star matter at zero and finite temperatures, and the determination of its equation of state. In part two, the properties of sequences of quark stars, divided into strange- and charm-quark stars, depending on quark-flavor content, are investigated. The strange stars are constructed for absolutely stable strange-quark matter, whose energy per baryon number lies below the one in $^{56}$Fe. In part three, the electrostatic potential of electrons inside and in the close vicinity outside of strange stars, which is of decisive importance for the possible existence of nuclear crusts on the surfaces of such stars, is computed. It is found that finite temperatures lead to a considerable reduction of the electrostatic electron potential at the surface of a strange star, which is accompanied by a strong reduction of the Coulomb barrier associated with the difference of the electrostatic potential at the surface of the star's strange-matter core and the base of the crust. This finding is of great importance for the stable existence of crusts on strange stars, since the Coulomb barrier plays the important role of preventing atomic nuclei bound in the nuclear crust from coming into contact with the star's strange-matter core, where atomic matter by hypothesis would be converted into strange matter. The structure and stability of quark stars against radial oscillations is discussed in part four, where it is found that charm-quark stars are unstable against radial oscillations. Thus no charm-quark stars (and, as is demonstrated too, no quark-matter stars possessing still higher central mass densities) can exist in nature.

1 Introduction

The hypothesis that strange quark matter may be the absolute ground state of the strong interaction (i.e., absolutely stable with respect to $^{56}$Fe) has been raised by Bodmer [1] and Witten [2]. On theoretical scale arguments, it is as plausible a ground state as the confined state of hadrons [2, 3, 4]. Even to the present day there is no sound scientific basis on which one can either confirm or reject Witten’s hypothesis, so that it remains a serious possibility of fundamental significance and for rare but exotic phenomena [5, 6, 7, 8, 9, 10, 11, 12]. (For a review of recent work, and a complete bibliography up to 1991, see Ref. [13].) If the hypothesis is true, then the very intriguing possibility of the existence of so-called strange-quark matter stars [2, 4, 11, 14, 15, 16, 17], made up of 3-flavor strange-quark matter whose energy per baryon number lies below the one of $^{56}$Fe, i.e. 930 MeV, opens up. They form a distinct and disconnected branch of compact stars, and are not part of the continuum of equilibrium configurations that include white dwarfs and neutron stars [2, 4, 14, 15]. More than that, some (in the most extreme case all) neutron stars could actually be strange stars. If so, pulsars are to be interpreted as rotating strange stars (strange pulsars) rather than rotating neutron stars [13]. Possible signatures of such objects could be rotational pulsar periods that lie significantly below one millisecond [9, 18], since the rotational periods of gravitationally bound neutron stars, constructed for a broad collection of realistic models for the nuclear equation of state, seem to lie above that limit [19, 20, 21, 22].

This paper deals with an investigation of the properties of quark-star matter at zero as well as non-zero temperatures, and the determination of the equation of state (i.e., pressure versus energy density relation) associated with it. The notion of quark-star matter comprises strange-quark star matter made up of $u, d$ and $s$ quarks [2, 4, 11, 14, 15, 16, 17] and charm-quark star matter [23], in which charm-quark states are populated in addition. Subsequently, the properties of the families of strange- and charm-matter stars, henceforth referred to, for brevity, as strange and charms stars, constructed for these equations of state are analyzed. There exist a few investiga-
tions dealing with the properties of strange stars that have been performed earlier than this one (for an overview, see, for example, Ref. [13]). Some of the major new aspects treated in this work concern the investigation of the structure and stability of strange and charm stars, being at zero as well as non-zero temperatures, against radial oscillations. Furthermore the influence of temperature on the electron chemical potential inside and outside of bare strange stars, which is of decisive importance for the possible existence of nuclear crusts on the surfaces of strange stars, is explored and its implications for strange pulsars are pointed out. The investigation is based on a systematic determination of a model for the equation of state of quark-star matter at finite temperature, whose properties are studied in great detail.

Our investigation is organized as follows. In Sect. 2 the description of quark-star matter, i.e. beta-equilibrated three- \((u,d,s)\) and four-flavor \((u,d,s,c)\) quark matter, at zero as well as finite temperatures is introduced. For the purpose of illustration, the special cases of cold quark matter made up of massless as well as massive quarks are discussed. A value for the bag constant of \(B^{1/4} = 145\) MeV, for which 3-flavor strange-quark matter is stable, has been chosen. For a strange quark mass of 150 MeV, this bag constant corresponds to an equilibrium energy per baryon number of strange matter of about 880 MeV. In other words, this choice represents strange matter being absolutely bound, by about 50 MeV, with respect to \(^{56}\text{Fe}\). Sequences of strange- and charm-quark stars are constructed in Sect. 3. In particular the impact of temperature on the structure of such objects is investigated. In Sect. 4 the electrostatic potential of electrons interior and exterior of strange stars is determined and its temperature dependence studied. Most important for the possible existence of a nuclear crust on the surface of a strange star, the width of the gap that exists between the surface and the base of the crust is determined for a variety of representative temperatures and electrostatic crust potentials. As a byproduct, the possibility of the conversion of hadronic matter (light atomic nuclei, like hydrogen and helium) that is accreted onto the surface of a bare strange star into strange matter is considered. Section 5 deals with an investigation of the stability of such stars against radial oscillations (acoustical modes). Our findings are summarized in Sect. 6. Mathematical details concerning the determination of the equation of state at finite temperature are given in the Appendix.

2 Description of Quark-Star Matter

In the following we present briefly the description of electrically charge neutral quark-star matter in equilibrium with respect to the weak interactions (i.e., beta-stable matter) at zero as well as finite external pressure and non-zero temperature. By quark-star matter we mean a Fermi gas of \(3A\) quarks which together constitute a single color-singlet baryon with baryon number \(A\). The dynamics of quark confinement is approximated by the bag model [24],

\[
p + B = \sum_{i=u,d,c,s,e^-} p_i ,
\] (1)
\[ \epsilon = \sum_{i=u,d,s,c,e^-} \epsilon_i + B, \] (2)

where \( p, \epsilon \) and \( B \) refer to external pressure, total internal energy density, and bag constant, respectively. The condition of electric charge neutrality reads

\[ 0 = \sum_{i=u,d,c,s,e^-} q_i n_i. \] (3)

The expressions for internal pressure, energy and number density of the quarks and leptons contained in the bag, \( p_i, \epsilon_i, \) and \( n_i \) respectively, are determined by the thermodynamic potentials, \( d\Omega_i = -S_i dT - P_i dV - N_i d\mu_i, \) from which one obtains (contributions of antiparticles are neglected. This is well justified for antiquarks since their chemical potentials are much larger than the considered temperatures (see also [25]). The situation is somewhat more delicate for the positrons, which too were found to contribute only very little.)

\[ \omega_i = \frac{\partial \Omega_i}{\partial V} = -\frac{g_i T}{2\pi^2} \int_0^\infty dk k^2 \ln \left[ 1 + e^{-\left(E_i(k) - \mu_i\right)/T} \right], \] (4)

\[ p_i = -\omega_i = \frac{g_i}{6\pi^2} \int_{m_i}^\infty dE \left( E^2 - m_i^2 \right)^{3/2} f_i(E), \] (5)

\[ n_i = -\frac{\partial \omega_i}{\partial \mu_i} = \frac{g_i}{2\pi^2} \int_{m_i}^\infty dE \sqrt{E^2 - m_i^2} f_i(E), \] (6)

where \( E_i^2(k) \equiv k^2 + m_i^2. \) (For the evaluation of the thermodynamic potential of a quark gas of \( N_c \) colors and \( N_f \) flavors to fourth order in the quark-gluon coupling, we refer to Ref. [26, 27].) The quantity \( m_i \) denotes the quark’s mass. The expression for the energy density of the system reads

\[ \epsilon_i = \frac{g_i}{2\pi^2} \int_{m_i}^\infty dE \sqrt{E^2 - m_i^2} f_i(E). \] (7)

The phase space factor \( g_i \) is equal to 2 (leptons) or 6 (quarks). The quantity \( f_i \) denotes the Fermi-Dirac distribution function, \( f_i(E) \equiv 1/[1 + \exp((E - \mu_i)/T)]. \) The baryon number density is given by

\[ n_A = \frac{1}{3} \sum_{i=u,d,s} n_i. \] (8)

Chemical equilibrium between the quark flavors and the leptons is maintained by the following weak reactions (and their inverse),

\[ d \rightarrow u + e^- + \bar{\nu}_e^- , \] (9)

\[ s \rightarrow u + e^- + \bar{\nu}_e^- , \] (10)

\[ s \rightarrow c + e^- + \bar{\nu}_e^- . \] (11)

The reactions

\[ s + u \leftrightarrow d + u , \] (12)

\[ c + d \leftrightarrow u + d \] (13)
contribute to the equilibration of flavors. The loss of neutrinos by the star implies that their chemical potential is equal to zero. Hence, one gets from Eqs. (9)-(13)

$$\mu_d = \mu_u + \mu_e^- \quad , \quad \mu_c = \mu_u \quad , \quad \mu_d = \mu_s . \tag{14}$$

Finally, the conservation of electric charge implies that

$$\mu_e^- = \mu_\mu^- . \tag{15}$$

The third of Eq. (14) motivates defining

$$\mu \equiv \mu_d = \mu_s . \tag{16}$$

For later purpose, we introduce the additional definitions

$$\eta_i \equiv \frac{\mu_i}{\mu} = \begin{cases} 1 - x & \text{if } i = u, c , \\ 1 & \text{if } i = d, s , \\ x & \text{if } i = e^- , \mu^- , \end{cases} \tag{17}$$

where

$$x \equiv \frac{\mu_e^-}{\mu} , \quad \text{and} \quad z_i \equiv \frac{m_i}{\eta_i \mu} = \frac{m_i}{\mu_i} . \tag{18}$$

### 2.1 Cold matter consisting of massless quarks

It is illustrative to apply, in a first step, the equations of the previous section to quark matter at zero temperature, assuming that all quark species are massless particles. Zero temperature implies that

$$f_i(E) \xrightarrow{T \to 0} \Theta(\mu_i - E) , \tag{19}$$

and Eqs. (4)-(7) lead to \((g_i = 6)\)

$$p_i = \frac{g_i}{24\pi^2} \mu^4 \eta_i^4 = \frac{1}{3} \epsilon_i , \tag{20}$$

$$n_i = \frac{g_i}{6\pi^2} \mu^3 \eta_i^3 . \tag{21}$$

One thus obtains from Eqs. (1) and (2) for the system’s equation of state the well known expression

$$p = \frac{\epsilon - 4B}{3} . \tag{22}$$

The condition of charge neutrality, Eq. (3), reads

$$\frac{2}{3} n_u - \frac{1}{3} (n_d + n_s) = 0 , \tag{23}$$
(no leptons are necessary to make the system electrically charge neutral). Finally, for zero external pressure, \( p = 0 \), one derives from Eq. (1) \( B = 3\mu^4/4\pi^2 \), and for the energy per baryon number in strange matter \([11]\)

\[
E_A \equiv \frac{\epsilon_i}{n_A} = \frac{4B}{(n_u + n_d + n_s)/3} = \frac{4B}{n_u} = \frac{4B\pi^2}{\mu^3} . \tag{24}
\]

From this relation one finds, for example, that bag constants of \( B = 57.5 \text{ MeV/fm}^3 \) \((B^{1/4} = 145 \text{ MeV})\) and \( B = 85.3 \text{ MeV/fm}^3 \) \((B^{1/4} = 160 \text{ MeV})\) place the energy per baryon number of strange matter consisting of massless \( u, d, \text{and} \ s \) quarks at 829 MeV and 915 MeV, respectively. In other words, these values represent strongly \((\sim 100 \text{ MeV})\) and weakly \((\sim 15 \text{ MeV})\) bound strange matter, at zero external pressure, and in all cases correspond to strange matter being absolutely bound with respect to \( ^{56}\text{Fe} \). (More details will be given in connection with the discussion of Figs. 1 and 2.)

### 2.2 Cold matter consisting of massive quarks

In the case of massive quarks, Eqs. (4)–(7) lead to \((i = u, d, c, s; e^-, \mu^-)\)

\[
p_i = \frac{g_i\mu_i^4\eta_i^4}{24\pi^2} \left[ \sqrt{1 - z_i^2} (1 - \frac{5}{2} z_i^2) + \frac{3}{2} z_i^4 \ln \frac{1 + \sqrt{1 - z_i^2}}{z_i} \right] , \tag{25}
\]

\[
n_i = \frac{g_i\mu_i^3\eta_i^3}{6\pi^2} (1 - z_i^2) \frac{3}{2} , \tag{26}
\]

\[
\epsilon_i = \frac{g_i\mu_i^4\eta_i^4}{8\pi^2} \left[ \sqrt{1 - z_i^2} (1 - \frac{1}{2} z_i^2) - \frac{z_i^4}{2} \ln \frac{1 + \sqrt{1 - z_i^2}}{z_i} \right] . \tag{27}
\]

The condition of electric charge neutrality, Eq. (3), reads now

\[
0 = \frac{2}{3} (n_u + n_{c}) - \frac{1}{3} (n_d + n_s) - (n_{e^-} + n_{\mu^-}) ,
\]

\[
= 2(1 - x^3)[1 + (1 - z_c^2)^{3/2}] - [1 + (1 - z_s^2)^{3/2}] - x^3[1 + (1 - z_\mu^2)^{3/2}] , \tag{28}
\]

and Eq. (1) leads to

\[
\frac{(p + B) 4\pi^2}{\mu^4} = (1 - x^4) \left[ 1 + \sqrt{1 - z_c^2}(1 - \frac{5}{2} z_c^2) + \frac{3}{2} z_c^2 \ln \frac{1 + \sqrt{1 - z_c^2}}{z_c} \right]
\]

\[
+ \left[ 1 + \sqrt{1 - z_s^2}(1 - \frac{5}{2} z_s^2) + \frac{3}{2} z_s^2 \ln \frac{1 + \sqrt{1 - z_s^2}}{z_s} \right]
\]

\[
+ \frac{x^4}{3} \left[ 1 + \sqrt{1 - z_\mu^2}(1 - \frac{5}{2} z_\mu^2) + \frac{3}{2} z_\mu^2 \ln \frac{1 + \sqrt{1 - z_\mu^2}}{z_\mu} \right] . \tag{29}
\]
The expressions of energy and baryon number density are given by

\[ \epsilon = 3p + 4B + \sum_{i=s,c,u} \epsilon_i - 3 \sum_{i=s,c,u} p_i \]  

(30)

\[ = 3p + 4B \]

\[ + \sum_{i=s,c,u} \frac{g_i \mu_i \eta_i^4}{4 \pi^2} z_i^2 [\sqrt{1 - z_i^2} - z_i^2 \ln \frac{1 + \sqrt{1 - z_i^2}}{z_i}] \]  

(31)

and

\[ n_A = \frac{1}{3} (n_u + n_d + n_s + n_c) \]

\[ = \frac{\mu^3}{3 \pi^2} \left[ (1 - x^2)(1 + (1 - z_e^2)^{\frac{3}{2}}) + (1 + (1 - z_s^2)^{\frac{3}{2}}) \right] . \]  

(32)

The first two terms on the right hand side of Eq. (31) represent the equation of state of massless-quarks, given by Eq. (22). The third term accounts for the finite masses of the muons, and the strange and charm quarks.

Figure 1 shows the energy per baryon number, \( E_A = \epsilon/n_A \), of strange matter at zero external pressure [3, 25], computed from Eq. (31). The influence of temperature is demonstrated for \( T = 30 \) MeV, which is typical for a newly formed neutron star in a supernova explosion [28, 29, 30]. (The equation of state of quark-star matter at finite temperature will be discussed in detail in Sect. 2.3.) The energy per baryon number of cold matter ranges from 830 to 950 MeV. For the purpose of comparison, we recall that the energy per baryon in \( ^{56}\text{Fe} \) amounts \( M(^{56}\text{Fe})c^2/56 = 930.4 \) MeV, where \( M(^{56}\text{Fe}) \) is the mass of the \( ^{56}\text{Fe} \) atom. Thus, with exception of the 950 MeV contour, all these curves correspond to strange matter that is absolutely stable, at zero external pressure, with respect to \( ^{56}\text{Fe} \). For a representative mass of the strange quark, \( m_s = 150 \) MeV, which was used in this work together with \( m_s = 0 \), this is the case for bag constants smaller than 75 MeV/fm\(^3\) (\( B^{1/4} = 155 \) MeV). The lower bound on \( B \), given by 57 MeV/fm\(^3\) (\( B^{1/4} = 145 \) MeV), is determined by the fact that the energy per baryon number of 2-flavor quark matter must be higher than the one of \( ^{56}\text{Fe} \). Otherwise \( ^{56}\text{Fe} \) would be made up of \( u \) and \( d \) quarks rather than nucleons. This condition also determines the termination points of these contours, which are located at those points where the contours cross the vertical line at \( B = 57 \) MeV/fm\(^3\) [3]. Finite temperatures (like finite quark masses, or external pressures, cf. Eq. (31)) increase both the energy density \( \epsilon \) of the bag as well as the baryon number density, \( n_A \). The impact of these increases are such that the energy contours are shifted toward smaller bag constants. This shift in \( B \), as can be seen in Figs. 1 and 2, is quite large and amounts \( \sim 20\% \), depending on the mass of the strange-quark. The impact of finite external bag pressures, \( p \), on the energy contours is illustrated in Fig. 2. A comparison with Fig. 1 shows that the energy contours are shifted toward smaller \( B \) values, too, which can be understood mathematically by means of combining Eqs.
Figure 1: Contours of fixed energy per baryon number (figures attached to these curves) of strange quark matter at zero external pressure. The solid and dashed curves refer to \( T = 0 \) and \( T = 30 \text{ MeV} \), respectively. The strange quark mass is plotted on the y-axis and the bag constant, \( B \), on the x-axis. The conversion of \( B \) from MeV/fm\(^3\) into units of MeV is accomplished by means of multiplying the former with powers of \( 1 = 197.3 \text{ MeV fm} \).

Figure 2: Same as Fig. 1, but for a finite external bag pressure of 50 MeV/fm\(^3\).
Figure 3: Relative densities of quarks \((q = u, d, c, s)\) and leptons \((l = e^-, \mu^-)\), \(n_i/n\) where \(n = \sum_{i=q,l} n_i\), in cold, beta-stable, electrically charge neutral quark-star matter as a function of energy density. (Here and in all subsequent calculations a bag constant of \(B^{1/4} = 145\) MeV has been chosen.)

(22) and (24) to \(B = (n_A E_A - 3p)/4\). (In the case of finite temperatures, or masses, the corresponding relation is obtained from Eq. (36).) From the physical point of view, this becomes clear by remembering that finite \(p\) values increase the pressure which acts on the bag from the outside, Eq. (1). So \(B\) can be reduced on the account of \(p\).

The relative quark/lepton composition of quark-star matter at zero temperature is shown in Fig. 3. All quark flavor states that become populated in such matter up to densities of \(10^{19}\) g/cm\(^3\) are taken into account. Since the Coulomb interaction is so much stronger than the gravitational, quark-star matter must be charge neutral to very high precision [8]. Therefore, any net positive quark charge must be balanced by a sufficiently large number of negatively charged quarks and leptons present in the system, as shown in Fig. 3. An enlargement of the upper portion of this figure is exhibited in Fig. 4. One sees that at lower densities the number of \(d\) quarks is somewhat larger than the one of \(s\) quarks, which is due to the finite mass of the latter. The behavior of \(n_d/n\) and \(n_s/n\) can be understood qualitatively from Eq. (25), which reveals that \(n_d/n_s = (1 - m_s/\mu_s)^{-3/2}\). Since \(m_s/\mu_s < 1\) it follows that \(n_d > n_s\) at all densities, and, secondly, \(n_d \xrightarrow{\infty} n_s\) from above since \(m_s/\mu_s \xrightarrow{\infty} 0\) (cf. Fig. 9). (Strange and charm quark masses of respectively 0.15 GeV and 1.2 GeV are assumed.) In contrast to the sensitive density dependence of lepton number, the abundances of \(u\), \(d\), and \(s\) quarks in strange matter vary only rather weakly with density. The situation is different for the \(c\) quarks whose concentration increases at threshold density extremely rapidly. At still higher densities it tends against the concentration of \(u\) quarks, and charge neutrality is nearly achieved by appropriate concentrations of quarks of both charge states only. The slight deficit of negative quark charge is delivered to the system by electrons and muons, whose concentrations increase monotonically for all
densities larger than the threshold density of the positively charged $c$ quarks.

### 2.3 Quark matter at finite temperature

To derive the equation of state of quark-star matter at finite temperature, up to about $T \sim 50$ MeV, we perform a perturbation expansion of pressure $p_i = p_i(\mu, x, T)$ and baryon density $n_i = n_i(\mu, x, T)$ about their zero-temperature values, $p_{i,0} \equiv p_i(\mu_0, x_0, T_0)$ and $n_{i,0} \equiv n_i(\mu_0, x_0, T_0)$, where $T_0 = 0$ [25]. By means of writing these functions in the form $\chi_i(\mu, x, T) \equiv \chi_i(\mu_0 - \Delta \mu, x_0 + \Delta x, T_0 + \Delta T)$, where $\chi_i$ stands for $p_i$ and $n_i$, expanding them in a Taylor series and keeping only the lowest order terms, one obtains

\[
\chi_i(\mu, x, T) \approx \chi_{i,0} + \frac{\partial \chi_i}{\partial \Delta \mu_{\mu_0}} \Delta \mu_{\mu_0,x_0,T_0} + \frac{\partial \chi_i}{\partial \Delta x_{\mu_0,x_0,T_0}} \Delta x_{\mu_0,x_0,T_0} + \frac{\partial^2 \chi_i}{\partial T^2_{\mu_0,x_0,T_0}} \Delta T_{\mu_0,x_0,T_0}, \tag{33}
\]

with $\chi_{i,0} \equiv \chi_i(\mu_0, x_0, T_0)$. Above, the definitions $\Delta \mu \equiv \mu_0 - \mu$ and $\Delta x \equiv x - x_0$ have been introduced, where $\mu_0 \equiv \mu(T_0)$ and $x_0 \equiv x(T_0)$. The major problem encountered now consists in calculating the expansion coefficients occurring in Eq. (33), $\partial \chi_i/\partial (\Delta \mu/\mu_0)$, $\partial \chi_i/\partial \Delta x$, and $\partial \chi_i/\partial (T/\mu_0)^2$. Their determination is outlined in detail in the Appendix. It should be noticed that since $\partial \chi_i/\partial (T/\mu_0) = 0$, which is shown in Ref. [31], both pressure and particle density depend in lowest-order only quadratically on temperature. After considerable algebra one arrives for pressure, particle density, and total energy density at the relations (the quantities $a$ and $b$ are defined in the Appendix)

\[
p_i = p_{i,0} + \frac{1}{6} g_i T^2 \mu_0^2 \left[ -a \eta_i^4 (1 - z_i^2)^{3} + b c_i \eta_i^3 (1 - z_i^2)^{3} \\
+ \frac{1}{2} \eta_i^2 (1 - \frac{1}{2} z_i^2) \right], \tag{34}
\]
Figure 5: Pressure isotherms versus mass density of electrically charge neutral quark-star matter. The impact of temperatures $T \leq 50$ MeV, which is significant at low nuclear densities only, is exhibited in Fig. 6.

\[ n_i = n_{i,0} + \frac{1}{2} g_i T^2 \mu_0 \left[ -a \eta_i^3 \sqrt{1 - z_i^2} + b c_i \eta_i^2 \sqrt{1 - z_i^2} + \frac{1}{3} \eta_i \right] , \quad (35) \]

\[ \epsilon = 3p + 4B + \sum_{i=s,c,p} \frac{g_i \mu_i^2 \eta_i^2}{2} \left( \frac{\hbar^2 \eta_i^2}{2\pi^2} z_i^2 \left( \sqrt{1 - z_i^2} - z_i^2 \ln \frac{1 + \sqrt{1 - z_i^2}}{z_i} \right) \right. \]
\[ \left. + T^2 (z_i^2 \sqrt{1 - z_i^2} (b c_i \eta_i - a \eta_i^2) + \frac{1}{6} z_i^3) \right) , \quad (36) \]

with the definition

\[ c_i \equiv \begin{cases} +1 & \text{if } i = e^-, \mu^- , \\ 0 & \text{if } i = d, s , \\ -1 & \text{if } i = u, c . \end{cases} \quad (37) \]

The comparison of these relations with the corresponding ones obtained for zero-temperature and massless quarks, derived in Sect. 2.1, immediately reveals the impact of finite temperatures and masses on the equation of state. Notice that in the limit of $T \to 0$, the zero-temperature equation of state (31) is obtained from Eq. (36). Furthermore, as outlined just above, the temperature dependence in the lowest-order expansion enters only quadratically in $T$.

The equation of state of strange matter at non-zero temperature, computed for Eq. (36), is shown in Fig. 5. There is a noticeable influence of temperature on the equation of state only near the saturation density of $\epsilon \sim 4B$, as can be seen from Fig. 6.

The expressions for particle density and pressure of electrons are given by (recall that $x(T) \equiv \mu_e-(T)/\mu_e(T)$, which reads at zero temperature $x_0 \equiv \mu_{e-,0}/\mu_0$)

\[ n_{e^-} = \frac{\mu_{0x_0^3}}{3\pi^2} + T^2 \mu_0 \left[ -ax_0^2 + bx_0^2 + \frac{1}{3} x_0 \right] , \quad (38) \]
Figure 6: Enlargement of the left portion of Fig. 5. The numbers associated to these pressure isotherms refer to temperature (in MeV). The value of the bag constant (here and for all other calculations) is $B = 1 \times 10^{14} \text{g/cm}^3 (=57 \text{MeV/fm}^3)$.

$$pe^- = \frac{\mu_0^2 x_0^2}{12\pi^2} + \frac{1}{3} T^2 \mu_0^2 [-ax_0^4 + bx_0^3 + \frac{1}{2} x_0^2]$$, (39)

which follow from Eqs. (34) and (35) applied to (massless) electrons, rather than massive quarks ($n_\text{e-} = x_0, z_\text{e-} = 0, c_\text{e-} = 1$, according to Eqs. (17), (18), and (37)). The temperature dependence of $n_\text{e-}$ for zero and finite external bag pressures, $p$, is exhibited in Fig. 7. Because finite $p$ values increase the system's total energy density (cf. Eq. (36)), fewer electrons are necessary in order to achieve electric charge neutrality and therefore the $n_\text{e-}$ isobars move downward with increasing pressures. Temperatures, typical for newly formed massive stars, increase $n_\text{e-}$ by roughly two orders of magnitude, depending on external pressure. The quadratic dependence of $n_\text{e-}$ on $T$, Eq. (38), is significant at lower temperatures. For larger $T$, the implicit temperature dependence of the expression in square brackets weakens the increase of $n_\text{e-}$ with temperature. The variation of electron chemical potential, $\mu_\text{e-}$, along the $n_\text{e-}$ isotherms is shown in Fig. 8. One sees that $\mu_\text{e-}$ deviates for temperatures $T \leq 50$ MeV from its zero-temperature value by at most 1 MeV ($\sim 4B$). The decrease of $\mu_\text{e-}$ with density reflects the fact that fewer electrons are needed in strange-quark matter at higher densities (cf. Fig. 3). Furthermore we notice the downward shift of the $\mu_\text{e-}$ isotherms, for a fixed density, with increasing temperature, which is due to the momentum tail of the Fermi-Dirac distribution function for $T > 0$.

The density and temperature dependence of the chemical potential of $d$ and $s$ quarks, $\mu$, is graphically depicted in Fig. 9. The former can be inferred qualitatively from Eq. (25), from which one gets $\mu = m_s(1 - n_s/n_d)^{-2/3}$. Slightly below the threshold density of $s$ quarks one has $n_s = 0$, and therefore $\mu_s = m_s$ there. The other extreme, high $s$ quark densities, is characterized by $n_s \to n_d$, as is known from Figs. 3 and 4. This implies that $\mu$ becomes very large in the high-density regime. In Sect. 3 it will be shown that stable strange stars possess central densities of at most
Figure 7: Density isobars of electrons, $n_{e-}$, versus temperature for different external pressure values, $p/(10^{15}\ \text{g/cm}^3) = 0, 0.1, 1, 10$, which are constant along each curve. The conversion of pressure from units of $\text{g/cm}^3$ to $\text{MeV/fm}^3$ is accomplished by dividing the former by $1.78 \times 10^{12}$.

Figure 8: Chemical potential of electrons, $\mu_{e-}$, versus energy density in electrically charge neutral quark-star matter at temperatures $T = 0, 30, \text{and } 50\ \text{MeV}$, which are constant along these curves.
Figure 9: Same as Fig. 8, but for the chemical potential, $\mu$ ($= \mu_d = \mu_s$), of $d$ and $s$ quarks (cf. Eq. (16)).

$\sim 2 \times 10^{15}$ g/cm$^3$. Therefore, from Fig. 9, $\mu$ never exceeds $\sim 500$ MeV in such stars. This value is considerably smaller than the mass of the charm quark. Concerning the impact of temperature on $\mu$, it is most significant at densities $\epsilon \sim 4B$ for the same reasons as already outlined in connection with the discussion of Figs. 5 and 6. Finally, finite temperatures reduce $\mu$ below its zero-temperature value. The reason is, again, the occurrence of the Fermi-Dirac function in Eq. (5) instead of the step function, leading to smaller chemical potentials for a fixed density. For the selected temperatures, this reduction amounts at most $\sim 100$ MeV.

3 Hydrostatic Equilibrium Sequences of Quark Matter Stars

The masses of the two families of quark-matter stars, strange and charm ones, as a function of central density are shown in Fig. 10. The latter family begins at a density of about $10^{17}$ g/cm$^3$ and ends at $4 \times 10^{18}$ g/cm$^3$. It should be noticed that higher-density families are obtained too for stars made up of matter that is purely gravitationally bound [32, 33]. One of the most significant differences between both species of stars concerns the existence of a minimum-mass configuration, of about $\sim 0.1 M_\odot$ [34], for the neutron star. In sharp contrast to this, the sequence of bare strange stars (no nuclear crusts), being bound by the strong interaction and not the gravitational force (the latter makes them only denser), does not possess a minimum-mass star. In fact, strange-matter objects can exist with baryon numbers in the enormous range of $10^2 \leq A \leq 10^{57}$ [3, 35]. The lower bound is determined by finite size effects, and the upper one is set by the gravitational interaction, which increases with $A$, and therefore makes strange stars possessing too large central densities unstable against gravitational collapse (cf. Sect. 5). (The situation is the same as for the purely
gravitationally bound neutron stars.)

Temperatures typical for newly formed pulsars influence the bulk properties of quark stars, such as mass and radius, only rather weakly, as can be seen from Figs. 10 and 11. Shown are star sequences that are obtained as solutions of the Oppenheimer-Volkoff equations [36], thus being in hydrostatic equilibrium. As is well known [32], hydrostatic equilibrium alone does not guarantee stability of a compact star. The still missing ingredient is a stability analysis against radial oscillations (acoustical modes), which will be performed in Sect. 5. There it will turn out that the charm-star sequence is

unstable against radial oscillations. Thus we are left with the possible existence of strange-quark stars only. The mass-radius relationship of the quark stars of Fig. 10 is shown in Fig. 11. For masses larger than $\sim 0.5 M_\odot$ it too bears a strong similarity with the one of neutron stars. Temperatures $T \leq 50$ MeV modify the properties of the more massive stars of the sequence only slightly. According to above, all stars possessing central densities larger than model ‘S’ are unstable against radial oscillations. The same inwardly-directed spiraling behavior was also obtained for stars constructed for baryon matter equations of state that were extrapolated to the super-high density regime [32], which shows again that this behavior is not specific to self-bound stars but rather manifests the dominant role of gravity at such high densities.

4 Electrons in Strange Stars

As shown in Sect. 2, because the strange-quark mass is larger than that of the $u$ and $d$ quarks, equilibrium strange matter contains an approximately equal mixture
of all three, with a slight deficit of $s$ quarks. A relatively small number of electrons is necessary to make the system electrically charge neutral. The electrons, being bound to the system by the electromagnetic interaction and not by the strong force, extend several hundred fermis beyond the boundary of the strange star \[14\], which itself has a surface thickness of the order of the strong interaction range. Associated with this electron layer at the surface of hypothetical strange stars is a strong electric field, which is radially outwardly directed. Most importantly for the glitch behavior and probably the cooling of strange pulsars (pulsars interpreted according to Witten’s hypothesis as rotating strange-matter stars) \[4, 17\], this layer can carry a solid nuclear crust suspended out of contact with the pulsar’s strange-matter core \[14\], which prevents the ion-quark matter reactions by which (atomic) crust matter would be converted into the true ground-state, strange matter. In the following, the behavior of the electrostatic potential of the electrons inside and in the close vicinity outside of strange stars is determined and, specifically, its temperature dependence studied. This analysis serves also to investigate, as a byproduct, the temperature dependence of the Coulomb barrier, associated with the difference of the electrostatic potential at the surface of the strange core and the base of the inner nuclear crust. (This constitutes an extension to finite temperatures of the zero-temperature analysis performed in Ref. \[14\].)
4.1 Impact of finite temperatures on the electrostatic potential of electrons

4.1.1 Inside strange stars

Firstly, the electrostatic potential of electrons, $V(r)$, inside a bare strange star is determined. For this purpose we recall that locally the energy of an electron sitting at the fermi surface is given by $\mathcal{E}(r) \equiv \mu_{e^{-}}(r) - eV(r)$ \cite{14, 25}, where $\mu_{e^{-}}(r)$ denotes the electron's radially dependent chemical potential. In equilibrium, $d\mathcal{E}(r)/dr = 0$. From the boundary conditions $V(r) \rightarrow 0$ and $\mu_{e^{-}}(r) \rightarrow 0$ \cite{14} it follows that $eV(r) = \mu_{e^{-}}(r)$ \cite{25}. The density dependence of the latter quantity has already been determined in Sect. 2. Plotting it as a function of radial distance, from the star's origin to its surface, leads to Fig. 12. It exhibits the behavior of $V(r)$ inside of strange stars, which possess representative gravitational masses, of $(1 - 1.6)M_\odot$ (see Fig. 11), and temperatures. Since $\mu_{e^{-}}$ decreases with density, Fig. 8, the electrostatic potential of electrons increases monotonically from the center toward the surface of strange stars. Finite temperatures influence the $eV(r)$ isotherms more significantly in the vicinity of the surface of strange stars than at their centers because the density is smallest there. For the heavier stars, which possess larger central densities, the isotherms are shifted downward, which is a consequence of the decreasing behavior of $\mu_{e^{-}}$ with density (Fig. 8). Another noteworthy feature is that independent of star mass (and thus, central star density), all isotherms referring to the same temperature terminate at the same value of $eV(R)$. This is indicated by the solid dots, which possess the same height for the same temperature. This independence of mass, or, in other words, of central star density, becomes clear from Fig. 8, which shows that...
the value of $\mu_{e^-}$ at the star's surface is determined only by the values of bag constant and temperature. It also explains the shifts of the termination points for increasing temperatures toward larger radii.

4.1.2 Surface region

In the second step, the behavior of $V(r)$ several hundred fermi inside and outside of the surface of a strange star is determined. For this purpose we recall that due to the rearrangement of electron charge there, the net positive charge of the quarks will be balanced locally by electrons only up to radial distances $r \leq R_m$ (star’s bulk matter part), where $R_m$ is only slightly smaller than the star’s radius, $R_m \lesssim R$. Beyond $R_m$, in the region $R_m \leq r \leq \infty$, the condition of electric charge neutrality is a global (rather than a local) one. In order to determine $R_m$, we note that from Poisson’s equation for radii in the range $R_m < r < \infty$,

$$\frac{d^2eV}{dr^2} = 4\pi e^2[n_{e^+}(r) - n_{e^-}(r)] \Theta(r - R_m)$$  \hspace{1cm} (40)

(the $dV/dr$ term can be neglected here; $3n_q \equiv 2n_u - n_d - n_s$, $n_q - n_{e^-} = 0$ for $r < R_m$) it follows that

$$\int_{R_m}^{R} dr n_q(r) = \int_{R_m}^{\infty} dr n_{e^-}(r)$$  \hspace{1cm} (41)

since $dV(R_m)/dr = dV(\infty)/dr = 0$. The first relation follows from the fact that $V(r)$ attains a maximum at $R_m$. The upper boundary in the second integral reflects the circumstance that the electrons extend beyond the surface of the strange star. Equation (41) can be transformed to

$$\int_{V(R_m)}^{V(R)} dV n_q = \int_{V(R_m)}^{\infty} dV n_{e^-}.$$  \hspace{1cm} (42)

Using $edV = d\mu_{e^-}$ and $n_{e^-} = \partial p_{e^-}/\partial \mu_{e^-}$ (cf. Eq. (5)), Eq. (42) can be written as

$$\int_{V(R_m)}^{V(R)} dV n_q = \frac{1}{e} \int_{\mu(R_m)}^{\mu(\infty)} d\mu_{e^-} \frac{\partial p_{e^-}}{\partial \mu_{e^-}}$$

$$= \frac{1}{e} [p_{e^-}(\infty) - p_{e^-}(R_m)].$$  \hspace{1cm} (43)

Because $R$ and $R_m$ differ only by a few hundred fermi [14], the density $n_q(r)$ in that range can be treated as being independent of $r$. Its value is therefore given, to a very good approximation, by $n_q(r) \simeq n_{e^-}(R_m)$. One thus obtains from Eq. (43)

$$eV(R, T) = \mu_{e^-}(R_m, T) - \frac{p_{e^-}(R_m, T)}{n_{e^-}(R_m, T)}.$$  \hspace{1cm} (44)

By means of the approximation $\mu_{e^-}(R_m, T) \simeq \mu_{e^-}(R, T)$ and substituting $p_{e^-}/n_{e^-}$ with Eqs. (38) and (39), one obtains for Eq. (44) (recall that the zero-temperature chemical potential of electrons, $\mu_{e^-}(T = 0)$, is abbreviated $\mu_{e^-,0}$)

$$eV(R, T) = \mu_{e^-}(R, T) - \frac{\mu_{e^-,0}^4(R) + 4\pi^2T^2\mu_{e^-,0}^2(R)[-ax_{e^-}^4(R) + bx_{e^-}^4(R) + \frac{1}{2}x_{e^-}^2(R)]}{4\mu_{e^-,0}^3(R) + 12\pi^2T^2\mu_{e^-,0}^3(R)[-ax_{e^-}^2(R) + bx_{e^-}^2(R) + \frac{1}{2}x_{e^-}^2(R)]}.$$  \hspace{1cm} (45)
where, according to Eq. (18) and Eq. (84) of the Appendix, the electron chemical potential at finite temperature is given by
\[
\mu_e(R, T) = \mu(R, T) x(R, T)
\]
(46)
\[
= \left( \mu_0(R) - a\pi^2 \frac{T^2}{\mu_0} \right) \left( x_0(R) + b\pi^2 \frac{T^2}{\mu_0^2} \right)
\]
(47)
In the special case of \( T = 0 \) one immediately obtains from Eq. (45) the simple relation [14]
\[
e V(R, T) \bigg|_{T=0} = \frac{3}{4} \mu_{e-, 0}(R)
\]
(48)
from which it follows that the electrostatic potential of electrons at the surface of the star’s strange-matter core is reduced relative to its value obtained by imposing the condition of local (instead of global) charge neutrality [14], which, due to the rearrangement of electron charge, holds only for radii \( r \leq R_m \) (cf. beginning of this section). As will be shown below (cf. Fig. 15), finite temperatures lead to an even stronger reduction of the electrostatic electron potential, which amounts at most 50\% for \( T \leq 50 \text{ MeV} \). From Eq. (45) one sees that this decrease has its origin in the reduction of \( \mu_{e-} \) with \( T \) (exhibited in Fig. 8), which is additionally strengthened by the second term on the right-hand-side of this equation. As an example, the values of \( \mu_{e-}(R, T = 0) \) and \( eV(R, T = 0) \), 18.8 and 14.1 MeV, respectively, reduce to 18.7 MeV and 9.5 MeV at \( T = 30 \text{ MeV} \), which shows that the temperature dependence of the second term in Eq. (45) prevails over the one of the first term.

Lastly, we determine \( V(r) \) in the regions \( R_m \leq r \leq R \) and \( R \leq r \leq R_{\text{crust}} \). The latter corresponds to distances that lie outside of the star’s strange-matter core. Two regions there are to be distinguished. The first one extends from the core’s surface, at \( r = R \), to that radial distance where the inner nuclear crust (referred to henceforth as the crust’s base) begins, denoted \( r = R_{\text{crust}} \). The associated width, \( R_{\text{gap}} \equiv R_{\text{crust}} - R \), is referred to henceforth as gap. The second region begins at \( R_{\text{crust}} \), and extends in the radial outward direction toward infinity. The behavior of the electrostatic potential in the surface region is determined by Poisson’s equation,
\[
\frac{d^2 eV}{dr^2} + \frac{2}{r} \frac{deV}{dr} = \frac{4\pi e^2}{3} \left\{ \left[ \frac{1}{\pi^2} [eV]^3 - \left(eV(R_m)\right)^3 \right] + T^2 \left[ eV - eV(R_m) \right] \right\} \Theta(r-R_m) \Theta(R-r)
\]
\[+ \left[ \frac{1}{\pi^2} (eV)^3 + T^2 eV \right] \Theta(r-R)\Theta(R_{\text{crust}}-r) \right\}.
\]
(49)
Notice that in the first term on the right hand side \( (R_m < r < R) \) the net charge density of electrons and quarks, \( n_{e-}(r) - n_q(r) \), enters, where \( n_q(r) \approx n_{e-}(R_m) = [eV(R_m)]^3/3\pi^2 \). By definition, the quark density is zero in the second region, \( R \leq r \leq R_{\text{crust}} \). The expression of \( n_{e-}(r) \),
\[
n_{e-}(r) = \frac{1}{3\pi^2} \mu_{e-}^3(r) + \frac{1}{3} \mu_{e-}(r) T^2
\]
\[= \frac{1}{3\pi^2} [eV(r)]^3 + \frac{1}{3} eV(r) T^2.
\]
(50)
is computed exactly from Eq. (5), treating the electrons as massless particles. A
analytical representation of $V(r)$ in the gap region can be obtained at zero temperature
if the $dV/dr$ term in Eq. (49) is ignored (a good approximation), i.e.,

$$\frac{d^2 eV}{dr^2} = \frac{4e^2}{3\pi} [eV(r)]^2 \Theta(r - R) \Theta(R_{\text{crust}} - r).$$

Its solution reads

$$eV(r) = \frac{C}{r - R + C/[eV(R)]}, \quad R \leq r \leq R_{\text{crust}},$$

with $C \equiv \sqrt{3\pi/2/e} = 5.013 \times 10^3$ MeV fm. It leads for a given crust potential,
$V(r) = V_{\text{crust}}$, to

$$R_{\text{gap}} \equiv R_{\text{crust}} - R = C \left( \frac{1}{eV_{\text{crust}}} - \frac{1}{eV(R)} \right).$$

Notice that a given value of $V_{\text{crust}}$ determines $R_{\text{crust}}$, and thus $R_{\text{gap}}$. It is obvious
that the gap disappears if the crust potential coincides with $V(R)$, the potential's
value at the surface of the strange core. In this case free ions would reach the star’s
strange-matter core without restraint.

4.1.3 Crust region

The electrostatic potential in the nuclear crust regime, $r \geq R_{\text{crust}}$, is constant. This
follows from the fact that the forces acting on the ions there, gravitational and electric,
must counterbalance each other at equilibrium. Since the former is tiny compared to
the electric force in the gap, one obtains $dV/dr = 0$ which implies that the electro-
static potential is constant there, that is, $V(r) \equiv V_{\text{crust}} (= \text{const})$. For what follows,
representative values of $V_{\text{crust}} = 5$ and 10 MeV have been chosen, together with zero
external potential [14].

4.2 Gap width at finite temperature

Figures 13–15 exhibit the behavior of $eV(r)$ in the close vicinity inside and outside
of $R$. The curves differ with respect to the temperature of the strange star and the
chosen value of $V_{\text{crust}}$. For zero temperature and a electrostatic crust potential of 5
MeV, as chosen here, a large gap of $R_{\text{gap}} = 810$ fm results. Larger values of $V_{\text{crust}}$,
reducing the difference of the potential at the star’s surface and the inner crust, lead
to narrower gaps. For example, a value of $eV_{\text{crust}} = 10$ MeV reduces $R_{\text{gap}}$ to 280 fm,
as can be seen from Fig. 14. This is consistent with the finding in Ref. [14]. Most
interestingly is the impact of finite temperatures on the gap. From Eq. (45) it is
already known that the potential’s value at the star’s surface, $V(R)$, is reduced in
this case. Figures 13–16 exhibit that this reduction amounts up to $\sim 50\%$ for the
Figure 13: Electrostatic potential of electrons in the close vicinity inside and outside of the surface of a strange star. The location of its surface is indicated by the vertical line. The figures assigned to these curves refer to temperature (in MeV). A representative value for the electrostatic crust potential, $eV_{\text{crust}} = 5$ MeV (horizontal line), which is constant (see text), has been chosen. The gap width extends from $\sim 40$ fm to about 800 fm, depending on temperature.

Figure 14: Same as Fig. 13, but for an electrostatic crust potential of 10 MeV.
temperatures under consideration. The associated reduction of $R_{\text{gap}}$ with temperature is rather strong. In fact, we find that the gap even shrinks to zero for plausible values of both $V_{\text{crust}}$ and temperature that would be typical for newly formed strange pulsars in supernovae.

In Ref. [14], a minimum value of $\sim 200$ fm was established as the lower bound on $R_{\text{gap}}$ necessary to guarantee the crust’s security against strong interactions with the star’s strange-matter core. Via Fig. 16 we find that a hot strange pulsar with $T = 30$ MeV cannot carry a nuclear crust whose electrostatic potential at the base is larger than $eV_{\text{crust}} \sim 0.1$ MeV. A somewhat cooler star of $T \sim 10$ MeV can carry only crusts with $V_{\text{crust}} \lesssim 4$ MeV. Finally, crust potentials in the range $8 - 12$ MeV are possible for stars with temperatures $T \lesssim 5$ MeV. In this connection it is interesting to recall that the upper limit on the density of the inner crust is determined by neutron drip, which occurs at about $4.3 \times 10^{11}$ g/cm$^3$, where free neutrons begin to drip out of the most stable nucleus, $^{118}$Kr ($Z = 36$), at that density [14]. Being electrically charge neutral, the neutrons can gravitate toward the star’s strange-matter core where they are converted into strange matter. The electrostatic potential in matter at such densities lies right in the above given range, $\sim 10$ MeV. Hence, we conclude that the constraint $V_{\text{crust}} \lesssim 10$ MeV established here provides another independent limit (besides the one set by neutron drip) on the maximum density of the nuclear crust that can be carried by a strange star. Accidentally, both sources lead to the same density limit. Applied to the formation of a crust on the surface of a bare strange pulsar formed in a supernova explosion, we are left with the important conclusion that its crust must be at rather low density in order to ensure a sufficiently large enough gap. In terms of mass, the crust will be much lighter than $\sim 10^{-5}M_{\odot}$ established for a strange pulsar possessing a nuclear crust whose density at the base is equal to neutron drip [14, 37].

As a further interesting aspect, the findings presented above permit a few simple
Table 1: Kinetic energy, $E_p$, acquired by a proton falling toward the surface of a bare strange star, for a few selected strange star masses.

Considerations concerning the accretion of matter onto the surface of a bare strange star being bound in a binary system, whose companion star is made up of ordinary matter. Furthermore, since the universe is a rather dirty environment, it seems plausible to assume that there might be strange stars that accrete some ambient (interstellar) material [14]. The idealized case of spherical accretion of a plasma, which consists of only protons and electrons, onto the surface of a bare, non-magnetized strange star (assuming no dissipation in the radiation flow of the infalling matter) has been considered in Ref. [16]. There it was estimated that under these circumstances, the kinetic energy of protons hitting the surface of a bare strange star is given by

$$E_p = \frac{138 \frac{M}{M_\odot}}{R_6 \sqrt{1 - 0.295 \frac{M}{M_\odot} R_6}} \text{ MeV},$$

where $R_6 = R/10^6$ cm and $M/M_\odot$ is the star’s mass in units of solar mass. Via Eq. (54) we estimate from our results (Fig. 11) that $E_p \lesssim 250$ MeV for a strange star possessing a typical pulsar mass. Further values are listed in Table 1. Such high energies would enable a proton to easily penetrate the maximum possible Coulomb barrier, which has a height of $e\Delta V \sim 15$ MeV, and to undergo a reaction with the star’s strange-matter core. (The barrier is defined as $e\Delta V = Z(eV(R,T) - eV_{crust})$, $Z = 1$ for protons.)
5 Stability Against Radial Oscillations

Below we give the equations that are to be solved to obtain the eigenfrequencies and eigenfunctions of radial normal modes of a massive star. The analysis is carried out on the basis of Einstein’s field equations for a metric of the form [32, 38]

\[ ds^2 = e^{2\nu(r)} dt^2 - e^{2\lambda(r)} dr^2 - r^2 \left( d\theta^2 + \sin^2 \theta \, d\phi^2 \right). \]  

(55)

The adiabatic motion of the star in its nth normal mode \((n = 0\) is the fundamental mode) is expressed in terms of an amplitude \(u_n(r)\) by

\[ \delta r(r, t) = e^{\nu(r)} u_n(r) e^{i\omega_n t} / r^2 , \]  

(56)

where \(\delta r(r, t)\) denotes small perturbations in \(r\). The quantity \(\omega_n\) is the star’s oscillation frequency, which we want to compute. The eigenvalue for \(u_n(r)\), which governs the normal modes, has the Sturm-Liouville form

\[ \frac{d}{dr} \left( \Pi(r) \frac{du_n(r)}{dr} \right) + \left( Q(r) + \omega_n^2 W(r) \right) u_n(r) = 0 . \]  

(57)

The functions \(\Pi(r)\), \(Q(r)\), and \(W(r)\) are expressed in terms of the equilibrium configurations of the star by

\[ \Pi = e^{(\lambda + 3\nu)} r^{-2} \Gamma P , \]  

(58)

\[ Q = -4e^{(\lambda + 3\nu)} r^{-3} \frac{dP}{dr} - 8\pi e^{3(\lambda + \nu)} r^{-2} P (\epsilon + P) \]  

\[ + e^{(\lambda + 3\nu)} r^{-2} (\epsilon + P)^{-1} \left( \frac{dP}{dr} \right)^2 , \]  

(59)

\[ W = e^{(3\lambda + \nu)} r^{-2} (\epsilon + P) . \]  

(60)

The quantities \(\epsilon\) and \(P\) in Eqs. (58)-(60) denote the energy density (total mass-energy) and the pressure of the stellar equilibrium configuration as measured by a local observer. The pressure gradient, \(dP/dr\), is obtained from the Oppenheimer-Volkoff equations. The symbol \(\Gamma\) denotes the varying adiabatic index at constant entropy, given by

\[ \Gamma = \left( \frac{\epsilon + P}{P} \right) \frac{\partial P}{\partial \epsilon} . \]  

(61)

The boundary conditions for Eq. (57) are

\[ u_n \sim r^3 \quad \text{at star's origin,} \quad r = 0 , \]  

(62)

\[ \frac{d u_n}{dr} = 0 \quad \text{at star's surface,} \quad r = R . \]  

(63)
Figure 17: Pulsation frequencies of the lowest four \((n = 0, 1, 2, \text{ and } 3)\) normal radial modes of quark matter stars as a function of central star density. For convenience, on the y-axis the quantity \(\Phi(a) \equiv \text{sign}(a) \log (1 + \text{abs}(a))\) with \(a \equiv (\omega_n/\text{sec}^{-1})^2\) is plotted instead of \(\omega_n^2\) itself.

Solving Eq. (57) subject to the boundary conditions (62) and (63) leads to the frequency spectrum \(\omega_n^2 (n = 0, 1, 2, \ldots)\) of the normal radial modes of a given stellar model. As a characteristic feature, the eigenfrequencies \(\omega_n^2\) form an infinite discrete sequence, i.e. \(\omega_n^2 < \omega_{n+1}^2\).

The four lowest-lying eigenfrequencies of quark stars are shown in Fig. 17. A comparison with their mass-central density relationship, Fig. 10, shows that these equilibrium configurations possess a characteristic mode of vibration of zero frequency \((\omega_n^2 = 0)\) when and only when the star's mass attains an extremum (critical point associated with an inflection point of mass), in agreement with the theorem of Harrison and Wheeler [32]. What is not known from the theorem, however, is which mode is possessing a zero point. Of course it must be the lowest-lying one which was previously stable, i.e., for which \(0 < \omega_n^2\). We find that it is the \(n = 0\) mode which becomes zero first at a density which corresponds to the maximum-mass strange quark star labeled 'S' in Figs. 10 and 11. Since \(\omega_5^2\) remains negative at all densities larger than this one, it follows that no quark matter stars can exist in nature that are more compact than the hypothetical strange stars. Specifically this rules out the possible existence of charm stars. In fact, as one sees from Fig. 17, going to higher and higher central star densities leads to the successive excitation of more and more unstable modes, i.e. \(\omega_n^2 < 0\) with \(n = 1, 2, 3, \ldots\), and thus no quark stars more massive than strange stars fulfill the condition \(\omega_n^2 > 0\) for all \(n \geq 0\), which is necessary for stability. This situation is analogous to that of hydrostatic equilibrium configurations in the neutron star sequence with central densities above that of the maximum-mass neutron star.

Finally, we point out that the instability of the charm stars is already indicated by the small values of the adiabatic index \(\Gamma\), defined in Eq. (61), of a ultrarelativistic quark gas [15]. By means of Eq. (22) and Figs. 5 and 10 one sees that \(\Gamma \approx 4/3\)
Figure 18: Amplitudes of the three lowest-lying eigenmodes of oscillation \((n = 0, 1, 2)\) of a strange star possessing a representative mass of \(M \sim 1.5 M_\odot\). The associated periods of radial oscillation are \(\tau_0 = 0.334\) ms, \(\tau_1 = 0.117\) ms, and \(\tau_2 = 0.075\) ms.

at charm-star densities. Stability of a stellar model with respect to small radial perturbations in the post-Newtonian approximation requires that \(\Gamma > 4/3 + 2M\kappa/R\), where \(\kappa \sim 1\) [39]. For typical masses and radii of charm stars, \(\sim 1.3 M_\odot\) and \(\sim 8\) km respectively (see Figs. 10 and 11), one finds \(2M\kappa/R \sim 0.5\), leading to \(\Gamma \gtrsim 5/3\) for such stars. Therefore, the less deeply analysis of the adiabatic index, performed in the post-Newtonian approximation, indicates that the family of charm stars may be unstable against radial oscillations. (Of course, from this simplified analysis alone one cannot definitely conclude that charm stars are unstable.)

Figure 18 exhibits the oscillation amplitudes of the first few vibrational modes of a strange-quark star with mass \(M \sim 0.5 M_\odot\). One sees that the number of nodes associated with an oscillation is equal to its order, \(n\), as determined by the mathematical structure of the eigenvalue equation. Specifically, the \(n = 0\) mode of oscillation is free of nodes. The corresponding periods of radial oscillation, \(\tau_n \equiv 2\pi/\omega_n\), whose values are listed in the figure caption, lie in the millisecond range, which is consistent with the findings of Ref. [40]. Table 2 shows that the oscillation periods are the smaller the lighter the strange star. Indeed, in the limit of vanishing star masses, which are obtained for \(\epsilon \rightarrow 4B\), the periods of all modes of strange stars go to zero, as shown in [41]. This behavior arises because \(\Gamma \rightarrow \infty\) when \(\epsilon \rightarrow 4B\), that is, \(\rho \rightarrow 0\), when the central density of the strange star tends toward its smallest possible value [15]. As known from Fig. 17, the frequency of the fundamental mode, \(\omega_0\), of the most massive strange star (labeled ‘S’ in Fig. 10) is zero. Therefore \(\tau_0 = \infty\) for that star model. The higher acoustical modes of vibration of the maximum-mass star are nonzero. They pass through zero at higher densities (Fig. 17).

The impact of finite temperatures on the periods of the fundamental radial oscillation, \(\tau_0\), of light strange stars is illustrated in Fig. 19. It is significant only for stars with masses \(M \lesssim 1 M_\odot\) (cf. Fig. 10), whose properties are most sensitive against
Figure 19: Lowest-lying periods of radial oscillation, \( \tau_0 \), of strange stars versus central star density, for star temperatures \( T = 0 \) and 50 MeV.

Table 2: Periods of radial oscillation, \( \tau_n \), of a few selected strange-star models.

variations of temperature. Interesting is a comparison of these periods with the corresponding ones of neutron stars. In the case of the latter, $\tau_0$, computed for a few selected nuclear equations of state [41], attains a minimum value of $\sim (0.3-0.4)$ msec at intermediate star masses. This is different for strange stars, due to their different generic mass-radius relationship, for which $\tau_0$ is the smaller the lighter the star (cf. Table 2). Both types of stars with masses $M \geq 1 M_\odot$ seem to possess periods of oscillation of the same magnitude.

6 Summary

The purpose of this work consists in an detailed investigation of the structure and stability of strange and charm stars at finite temperatures. It is found that temperatures $T \leq 50$ MeV modify the equation of state significantly only at energy densities that are close to $\sim 4B$, i.e., at small external bag pressures. The situation is different for the electrons since they are bound to the system by the electromagnetic interaction rather than the strong force, as is the case for the quarks. Correspondingly the electron density varies for temperatures in the range $0 \leq T \leq 50$ MeV between one and two orders of magnitude. A change of the density of electrons is accompanied by a change of their chemical potential, which, however, is smaller than $\lesssim 1$ MeV. As a consequence of the weak temperature dependence of the equation of state, the bulk properties of sequences of strange stars too exhibit only a weak dependence on temperature. The quark/lepton composition of quark-star matter is determined up to those densities at which even charm-quark states become populated. We find that this takes place at densities slightly larger than $10^{17}$ g/cm$^3$. In order to fulfill the condition of electric charge neutrality, there is only little need for electrons. Muons are completely absent in strange-star matter, and become populated only at densities larger than the threshold density of charm quarks.

Of crucial importance for the existence of nuclear crusts on the surfaces of bare strange stars is the existence of a Coulomb barrier associated with the difference of the electrostatic potential at the surface and the base of the crust. It is found that finite temperatures lead to a considerable reduction of the Coulomb barrier, which favors the tunneling of ions (atomic nuclei) bound in the nuclear crust toward the strange star surface. In fact, the electrostatic potentials at the surface of a hot strange star and at the base of its inner crust may even become equal at temperatures that are typical for newly formed pulsars, $T \sim (30 - 50)$ MeV. Thus, the Coulomb barrier, which prevents the ions in the crust from coming into contact with the star's strange matter core, disappears and consequently conversion of confined baryonic matter into strange matter is not prohibited any longer. Therefore, we conclude that hot strange stars are unlikely to possess nuclear crusts as long as their temperatures are larger than about 5 MeV, depending on the value of the crust's electrostatic potential at its base.

Another important topic of this article consists in performing a stability analysis of quark-matter stars against radial oscillations. It is found that the fundamental eigenmode passes through zero at the density of the most massive strange-star. It is
positive at all densities smaller than this one. Thus, strange stars are stable against radial oscillations. The situation is different for all quark stars having central densities larger than the maximum-mass strange star. For all such configurations the fundamental mode is found to be unstable. More than that, going to higher and higher central star density leads to the successive excitation of higher-lying eigenmodes. We thus arrive at the very important conclusion that no quark-matter stars can exist in nature other than the hypothetical strange stars. Specifically, this rules out the possible existence of charm-quark stars.

Finite-Temperature Expansion

The coefficients occurring in the expansion of pressure, Eq. (33), are obtained from Eqs. (4) and (5) as follows,

\[
\frac{\partial p_i}{\partial \Delta \mu} = -\frac{g_i \mu \eta_i}{2\pi^2} \int_{m_i}^{\infty} dE \frac{E}{E^2 - m_i^2} f_i(E) \tag{64}
\]

\[
\rightarrow \quad T \to 0 \quad -\frac{g_i \mu \eta_i}{2\pi^2} \int_{m_i}^{\mu T} dE \frac{E}{E^2 - m_i^2} f_i(E) \tag{65}
\]

\[
= -\frac{g_i \mu \eta_i}{2\pi^2} \frac{1}{3} (\mu \eta_i)^2 - m_i^2 \frac{3}{2} \tag{66}
\]

Notice that at finite temperatures the quantity \( \eta_i \) is given by (cf. Eq. (17) and Sect. 2.3)

\[
\eta_i = \begin{cases} 
1 - (x_0 - \Delta x) & \text{if } i = u, c, \\
1 & \text{if } i = d, s, \\
x_0 + \Delta x & \text{if } i = e^-, \mu^-, 
\end{cases} \tag{67}
\]

All those quantities not defined here are explained in Sect. 2. From Eq. (66) one gets, using Eq. (18),

\[
\left. \frac{\partial p_i}{\partial \Delta \mu} \right|_{\mu_0, x_0, T = 0} = -\frac{g_i}{6\pi^2} \mu_0^4 \eta_i (1 - z_i^2) \frac{3}{2} \tag{68}
\]

The second coefficient reads

\[
\frac{\partial p_i}{\partial \Delta x} = \frac{g_i c_i \mu}{2\pi^2} \int_{m_i}^{\infty} dE \frac{E}{E^2 - m_i^2} f_i(E) \tag{69}
\]

\[
\rightarrow \quad T \to 0 \quad \frac{g_i c_i \mu_0}{2\pi^2} \int_{m_i}^{\mu_0 T} dE \frac{E}{E^2 - m_i^2} f_i(E) \tag{70}
\]

and thus

\[
\left. \frac{\partial p_i}{\partial \Delta x} \right|_{\mu_0, x_0, T = 0} = \frac{g_i c_i}{6\pi^2} \mu_0^4 \eta_0^2 (1 - z_i^2) \frac{3}{2} \tag{71}
\]

The third coefficient is obtained from

\[
\frac{\partial p_i}{\partial T^2}_{\mu_0} = \frac{\mu_0^2 g_i}{12\pi^2} \left\{ \int_{-\infty}^{\infty} d\xi \frac{\xi (\xi T + \mu \eta_i)^3}{1 + e^\xi} \frac{e^\xi}{1 + e^\xi} \frac{1}{T} \right. \\
- \left. \frac{3}{2} m_i^2 \int_{-\infty}^{\infty} d\xi \frac{\xi (\xi T + \mu \eta_i)}{1 + e^\xi} \frac{e^\xi}{1 + e^\xi} \frac{1}{T} \right\} \tag{72}
\]

where the transformation \( \xi \equiv (E - \mu \eta_i)/T \) has been introduced. For the zero-temperature coefficient one gets

\[
\left. \frac{\partial p_i}{\partial T^2}_{\mu_0} \right|_{\mu_0, x_0, T = 0} = \frac{\mu_0^2 g_i}{12\pi^2} \left\{ 3(\mu_0 \eta_i)^2 \frac{\pi^2}{3} - \frac{3}{2} m_i^2 \frac{\pi^2}{3} \right\} \tag{73}
\]

\[
= \frac{g_i}{12} \mu_0^4 \eta_i^2 \left( 1 - \frac{1}{2} z_i^2 \right) \tag{74}
\]
The coefficients occurring in the expansion of particle density are obtained from
Eq. (5), and are given by

\[ \frac{\partial n_i}{\partial \Delta \mu} = -\frac{g_i \mu \eta_i}{2\pi^2} \int_{m_i \mu \eta_i}^{\infty} d\xi \left( \xi T + \mu \eta_i \right) \sqrt{(\xi T + \mu \eta_i)^2 - m_i^2} \frac{e^\xi}{(1 + e^\xi)^2}, \quad (75) \]

\[ \frac{\partial n_i}{\partial \Delta \mu} \bigg|_{\mu_0, x_0, T=0} = -\frac{g_i \mu \eta_i}{2\pi^2} \mu_0 \eta_i \sqrt{\mu_0 \eta_i} \int_{-\infty}^{\infty} d\xi \frac{e^\xi}{(1 + e^\xi)^2} \quad (76) \]

and

\[ \frac{\partial n_i}{\partial \Delta x} = \frac{g_i c_i}{2\pi^2} \mu_0 \eta_i^2 \sqrt{1 - z_i^2}, \quad (77) \]

which has the same mathematical structure as Eq. (75). At zero temperature it reduces to

\[ \frac{\partial n_i}{\partial \Delta x} \bigg|_{\mu_0, x_0, T=0} = \frac{g_i c_i}{2\pi^2} \mu_0 \eta_i^2 \sqrt{1 - z_i^2}. \quad (79) \]

Finally, from

\[ \frac{\partial n_i}{\partial \Delta x} = \frac{g_i \mu \eta_i}{4\pi^2} \int_{m_i \mu \eta_i}^{\infty} d\xi \frac{\xi}{T} \left( \xi T + \mu \eta_i \right) \sqrt{(\xi T + \mu \eta_i)^2 - m_i^2} \frac{e^\xi}{(1 + e^\xi)^2} \]

\[ = \frac{g_i \mu \eta_i}{4\pi^2} \left( \int_{-\infty}^{+\infty} d\xi \frac{\xi}{T} \left( \xi T + \mu \eta_i \right) \sqrt{(\xi T + \mu \eta_i)^2 - m_i^2} \frac{e^\xi}{(1 + e^\xi)^2} \right) \quad (80) \]

one gets

\[ \frac{\partial n_i}{\partial \Delta x} \bigg|_{\mu_0, x_0, T=0} = \frac{g_i \mu \eta_i}{2\pi^2} \mu_0 \eta_i \frac{\pi^2}{3} = \frac{g_i}{6} \mu_0 \eta_i. \quad (82) \]

The expansion coefficients of particle density enter in the condition of electric charge neutrality, Eq. (3), written at finite temperature,

\[ 0 = \sum_i q_i \left\{ n_{i,0} \frac{\partial n_i}{\partial \Delta \mu} \bigg|_{\mu_0, x_0, T_0} + \frac{\Delta \mu}{\mu_0} + \frac{\partial n_i}{\partial \Delta x} \bigg|_{\mu_0, x_0, T_0} \Delta x + \frac{\partial n_i}{\partial T^2} \bigg|_{\mu_0, x_0, T_0} \frac{T^2}{\mu_0^2} \right\}. \quad (83) \]

Now, Eq. (83) holds at all temperatures \( T \geq 0 \). In the special case of \( T = 0 \) one has \( \Delta \mu = \Delta x = 0 \), and thus it follows that \( \sum_i q_i n_{i,0} = 0 \), in agreement with Eq. (3). Since the sum of the remaining three terms on the right hand side of Eq. (83) must
be equal to zero at any temperature different from zero, all three must possess the same functional temperature dependence. We thus make the ansatz

$$\frac{\Delta \mu}{\mu_0} = a \pi^2 \left( \frac{T}{\mu_0} \right)^2, \text{ and } \Delta x = b \pi^2 \left( \frac{T}{\mu_0} \right)^2.$$  \hfill (84)

Inserting Eq. (84) in Eq. (83) leads to an equation of the form

$$0 = \tilde{A} a + \tilde{B} b - \tilde{Q},$$  \hfill (85)

where

$$\tilde{A} \equiv \pi^2 \sum_i q_i \frac{\partial n_i}{\partial \Delta \mu} \bigg|_{\mu_0, x_0, T=0} = 1 - \sqrt{1 - z_t^2} + 3 x_0 (x_0^2 - 2 x_0 + 2) + 2 (1 - x_0^3) \sqrt{1 - z_{x_0}^2} - x_0^2 \sqrt{1 - z_\mu^2},$$  \hfill (86)

$$\tilde{B} \equiv \pi^2 \sum_i q_i \frac{\partial n_i}{\partial \Delta x} \bigg|_{\mu_0, x_0, T=0} = -2 - x_0 (4 - 3 x_0) + 2 (1 - x_0^2) \sqrt{1 - z_{x_0}^2} + x_0^2 \sqrt{1 - z_\mu^2},$$  \hfill (87)

$$\tilde{Q} \equiv -\sum_i q_i \frac{\partial n_i}{\partial T} \bigg|_{\mu_0, x_0, T=0} = \frac{1}{3} (1 - 5 x_0).$$  \hfill (88)

To derive the pressure-energy density relation at finite temperature, we start from Eq. (1), which reads now ($p$ denotes an external pressure acting on the quark bag)

$$p + B = \sum_i \left[ p_i,0 + \left\{ \frac{\partial p_i}{\partial \Delta \mu} \bigg|_{\mu_0, x_0, T_0} \frac{\Delta \mu}{\mu_0} + \frac{\partial p_i}{\partial \Delta x} \bigg|_{\mu_0, x_0, T_0} \Delta x + \frac{\partial p_i}{\partial T} \bigg|_{\mu_0, x_0, T_0} \frac{T^2}{T^2} \right\} \right].$$  \hfill (89)

Since at zero temperature $p + B = \sum_i p_i,0$, it follows that the expansion in curly brackets must vanish identically. By means of Eq. (84) one obtains, in analogy to Eq. (85),

$$0 = \tilde{C} a + \tilde{D} b - \tilde{P},$$  \hfill (90)

where

$$\tilde{C} \equiv \pi^2 \sum_i \frac{\partial p_i}{\partial \Delta \mu} \bigg|_{\mu_0, x_0, T=0} = (1 - x_0)^4 + \frac{1}{3} x_0^4 + 1 + (1 - z_{x_0}^2)^{\frac{3}{2}} + (1 - x_0)^4 (1 - z_{x_0}^2)^{\frac{3}{2}} + \frac{1}{3} x_0^4 (1 - z_{\mu}^2)^{\frac{3}{2}},$$  \hfill (91)

$$\tilde{D} \equiv \pi^2 \sum_i \frac{\partial p_i}{\partial \Delta x} \bigg|_{\mu_0, x_0, T=0}$$
\[
\begin{align*}
\epsilon &= (1 - x_0)^3 - \frac{1}{3} x_0^3 + (1 - x_0)^2(1 - z_s^2)^{\frac{3}{2}} - \frac{1}{3} x_0^3(1 - z_\mu^2)^{\frac{3}{2}}, \\
\bar{\rho} &\equiv -\sum_i \left. \frac{\partial p_i}{\partial \mu^2} \right|_{\mu_c, x_0, T=0} \\
&= \frac{1}{2} \left[ (1 - x_0)^2 + 1 + (1 - \frac{1}{2} z_s^2) + \frac{1}{3} x_0^2 + (1 - x_0)^2(1 - \frac{1}{2} z_\mu^2) + \frac{1}{3} x_0^2(1 - \frac{1}{2} z_\mu^2) \right].
\end{align*}
\]

Muons and c quarks occur in the system only at densities larger that \(3.8 \times 10^{17} \text{ g/cm}^3\) and \(1.1 \times 10^{17} \text{ g/cm}^3\), respectively. Quark matter at lower densities consists of only \(u, d, s\) quarks and electrons. For such matter the above coefficients, \(\bar{A}\) through \(\bar{P}\), are given by the simpler relations

\[
\begin{align*}
\bar{A} &= 1 - \sqrt{1 - z_s^2} - 3x_0(x_0^2 - 2x_0 + 2), \\
\bar{B} &= 2 - x_0(4 - 3x_0), \\
\bar{Q} &= -x_0, \\
\bar{C} &= (1 - x_0)^4 + \frac{1}{3} x_0^4 + 1 + (1 - z_s^2)^{\frac{3}{2}}, \\
\bar{D} &= (1 - x_0)^3 - \frac{1}{3} x_0^3, \\
\bar{P} &= \frac{1}{2} \left[ (1 - x_0)^2 + 1 + (1 - \frac{1}{2} z_s^2) + \frac{1}{3} x_0^2 \right].
\end{align*}
\]

Equations (85) and (90) constitute two relations for the two unknowns \(a\) and \(b\). Solving for them and inserting the results into Eqs. (33) and (84) leads to the expressions for \(p_i\) and \(n_i\) given by Eqs. (34) and (35), respectively. Finally, the expression for the energy density is obtained from Eqs. (1) and (2) which, for this purpose, are combined to

\[
\epsilon = 3p + 4B + \sum_{i=e, s, \mu} (\epsilon_i - 3p_i).
