Neutrinoless Double Beta Decay in Light of SNO Salt Data

Hitoshi Murayama* and Carlos Peña-Garay

School of Natural Sciences, Institute for Advanced Study, Einstein Dr, Princeton, NJ 08540, USA

(Dated: February 1, 2008)

In the SNO data from its salt run, probably the most significant result is the consistency with the previous results without assuming the $^{3}$B energy spectrum. In addition, they have excluded the maximal mixing at a very high confidence level. This has an important implication on the double beta decay experiments. For the inverted or degenerate mass spectrum, we find $|\langle m_{\nu}\rangle_{ee}| > 0.013$ eV at 95% CL, and the next generation experiments can discriminate Majorana and Dirac neutrinos if the inverted or degenerate mass spectrum will be confirmed by the improvements in cosmology, tritium data beta decay, or long-baseline oscillation experiments.

In the past five years, there had been an amazing progress in neutrino physics. The atmospheric neutrinos showed a large up-down asymmetry in the SuperKamiokande (SK) experiment which came as the first significant evidence for a finite neutrino mass [1] and hence the incompleteness of the Standard Model of particle physics. SuperKamiokande also improved the accuracy in solar neutrino studies greatly using the elastic scattering (ES) process. The Sudbury Neutrino Observatory (SNO) experiment has studied the charged-current (CC) and neutral-current (NC) process in addition to the ES process, and has shown that the solar neutrinos change their flavors from the electron type to other active types (muon and tau neutrinos) [2]. Finally, the KamLAND reactor anti-neutrino oscillation experiments reported a significant deficit in reactor anti-neutrino flux over approximately 180 km of propagation [3]. Further combined with the pioneering Homestake experiment [4] and Gallium-based experiments [5], the decades-long solar neutrino problem [6] appears solved. The so-called Large Mixing Angle (LMA) solution [7], where the electron neutrinos produced at Sun’s core propagate adiabatically to a heavier mass eigenstate due to the matter effect [8], is the only viable explanation of the data.

On September 7, 2003, SNO published the result from their salt run with an enhanced sensitivity to the NC process [9]. Most importantly, the new result agrees well with previous results, confirming the LMA solution to the solar neutrino problem. In addition, they have reported a much better determination of the mixing angle $\theta_{12}$, which excludes the maximal mixing $\theta_{12} = \pi/4$ at a very high significance: 5.4 sigma.

The exclusion of the maximal mixing has an important impact on another crucial question in neutrino physics: Is neutrino its own anti-particle? If yes, neutrinos are Majorana fermions; if not, Dirac. This question is even deeper than it sounds. For instance, if neutrinos and anti-neutrinos are identical, there could have been a process in Early Universe that affected the balance between particles and anti-particles, leading to the matter anti-matter asymmetry we need to exist. In fact, so-called leptogenesis models directly link the Majorana nature of neutrinos to the observed baryon asymmetry [10].

This question can in principle be resolved if a neutrinoless double beta decay is observed. Because such a phenomenon will violate the lepton number by two units, it cannot be caused if the neutrino is different from the anti-neutrino [11]. Many experimental proposals exist that will increase the sensitivity to such a phenomenon dramatically over the next ten years [12]. The crucial question is if a negative result from such experiments can lead to a definitive statement about the nature of neutrinos. In particular, the matrix element of neutrinoless double beta decay is proportional to the effective electron-neutrino mass [13]

$$\langle m_{\nu}\rangle_{ee} = m_{1}U_{e1}^{2} + m_{2}U_{e2}^{2} + m_{3}U_{e3}^{2},$$  \hspace{1cm} (1)$$

which may have cancellation among three terms that makes it difficult to assess the result of a negative search. However, the exclusion of the maximal mixing in $\theta_{12}$ actually helps to eliminate such an unfortunate situation. Note that the proposed experiments are aiming at the sensitivity reaching $|\langle m_{\nu}\rangle_{ee}| \sim 0.01$ eV [13].

Within three generations of neutrinos and given all neutrino oscillation data [39], there are three possible mass spectra: degenerate, normal hierarchy and inverted hierarchy (see Fig. [1]). Given that the third mixing angle $\theta_{13} = \arcsin |U_{e3}|$ is known to be small from the CHOOZ limit [18], one can obtain a lower bound on the effective electron-neutrino mass. For the

---

*On leave of absence from Department of Physics, University of California, Berkeley, California 94720, USA
we can again ignore \( m \) relative to two other terms, and find

\[
|\langle m_\nu^{ee}\rangle| \simeq |mU_{e1}^2 + mU_{e2}^2| \\
\geq m(\left|U_{e1}\right|^2 - \left|U_{e2}\right|^2) = m \cos 2\theta_{12}.
\]

For the inverted hierarchy, \( m_1 \simeq m_2 \geq \sqrt{\Delta m^2_{\text{atm}}} \), and we can again ignore \( m_3U_{e3}^2 \) relative to two other terms. Therefore,

\[
|\langle m_\nu^{ee}\rangle| \geq \sqrt{\Delta m^2_{\text{atm}}\left|U_{e1}\right|^2 + \left|U_{e2}\right|^2} \\
\geq \sqrt{\Delta m^2_{\text{atm}}\left(\left|U_{e1}\right|^2 - \left|U_{e2}\right|^2\right)^2} = \sqrt{\Delta m^2_{\text{atm}}} \cos 2\theta_{12}.
\]

Note that the bound for the inverted hierarchy is weaker than that for the degenerate spectrum by definition, because the degeneracy requires \( m \gtrsim \sqrt{\Delta m^2_{\text{atm}}} \). Therefore, Eq. (3) is our master equation for most of our discussions.

Unfortunately, for the normal hierarchy, one cannot obtain a similar rigorous lower limit. On the other hand, the improvement in the cosmological data \([15] \) and the KATRIN experiment on the end point of the trium beta decay \([20] \) may positively establish the degenerate spectrum, or the long baseline neutrino oscillation experiments may positively establish the inverted hierarchy \([21] \). If either of them happens, and if the neutrinoless double beta won't be seen within these bounds, the neutrinos will be found to be Dirac particles \([41] \).

\( \cos 2\theta_{12} \) now has a robust lower bound given the new SNO result. To the best of our knowledge, it was pointed out first in \([23] \) that the less than maximal mixing leads to a lower bound on \( |\langle m_\nu^{ee}\rangle|^2 \) for the degenerate and inverted spectra. More recent papers \([24] \) studied the bound quantitatively before the recent SNO result when the lower bound was not quite robust, because the exclusion of the maximal mixing was reported at different confidence levels among different analyses and depended crucially on Homestake data \([4] \).

There are obviously two main ingredients in the lower bound. One is \( \Delta m^2_{\text{atm}} \) from SuperKamiokande experiment which had recently been updated \([25] \), and the other is \( \theta_{12} \) from the solar neutrino data which includes the recent SNO result. The last ingredient is \( \theta_{13} \) which we assume to be zero throughout our discussions. We will come back to the little effect of non-vanishing \( \theta_{13} \) at the end of the letter.

First on \( \Delta m^2_{\text{atm}} \). The analysis of the atmospheric (SK) and accelerator (K2K) data was done in the general case of 3\( \nu \) oscillations in \([15] \), and we show the marginalized \( \Delta \chi^2 \) as a function of \( \sqrt{\Delta m^2_{\text{atm}}} \) in the right pane of Fig. 2. The constraint \( \theta_{13} = 0 \) does not modify the shape of these functions. This analysis uses the data available before updates this summer \([25] \). The SK preliminary analysis of atmospheric data show a shift of the allowed region to lower \( \Delta m^2_{\text{atm}} \), due to several improvements in their analysis: new neutrino flux with updated primary cosmic ray flux, hadron interaction model and calculation methods (3D), and improved neutrino interactions, detector simulation and event reconstruction. We included the SK update \([16] \).

Second on \( \theta_{12} \). The analysis of solar and reactor data is done as described in \([15] \), except that \( \theta_{13} \) is set to zero, the Gallium rate is updated \([5] \) and the latest SNO data (NC, CC and ES measured in phase-II \([9] \) is included \([26] \). The \( \Delta \chi^2 \) is shown as a function of \( \cos 2\theta_{12} \) in the right pane of Fig. 2.

Combining \( \Delta m^2_{\text{atm}} \) and \( \theta_{12} \) discussed above, we obtain the final result on the effective electron-neutrino mass. The lower limit

\[
\Delta \chi^2 = \chi^2_{\text{max}} - \chi^2_{\text{min}} \leq \chi^2_{\text{max}} - \chi^2_{\text{min}}
\]

is shown as function of \( \cos 2\theta_{12} \) in the right pane of Fig. 2. The

\[
\begin{align*}
\Delta \chi^2 & \leq \chi^2_{\text{max}} - \chi^2_{\text{min}} \\
& \leq \chi^2_{\text{max}} - \chi^2_{\text{min}}
\end{align*}
\]

is shown as function of \( \cos 2\theta_{12} \) in the right pane of Fig. 2.

\[
\begin{align*}
\Delta \chi^2 & \leq \chi^2_{\text{max}} - \chi^2_{\text{min}} \\
& \leq \chi^2_{\text{max}} - \chi^2_{\text{min}}
\end{align*}
\]

is shown as function of \( \cos 2\theta_{12} \) in the right pane of Fig. 2.

\[
\begin{align*}
\Delta \chi^2 & \leq \chi^2_{\text{max}} - \chi^2_{\text{min}} \\
& \leq \chi^2_{\text{max}} - \chi^2_{\text{min}}
\end{align*}
\]

is shown as function of \( \cos 2\theta_{12} \) in the right pane of Fig. 2.
Finally, the last term cannot be negative given the CHOOZ limit and only strengthens our limit. Overall, our lower bound can change at most by 8%.

The bound on $\langle |m_{ee}| \rangle$ is expected to improve further as more data will become available. As for long-baseline (LBL) accelerator-based neutrino oscillation experiments, K2K will double the data set, while MINOS, ICARUS, and OPERA are expected to come online around 2005. If approved, the neutrino beam from J-PARC will be available around 2007. They will improve the accuracy on $\Delta m^2_{\text{atm}}$ dramatically [28]. SNO will install dedicated Neutral Current Detector (NCD) this fall, which will allow event-by-event separation of CC/ES and NC events and lead to a more accurate measurement of $\theta_{12}$ [29]. Later, measurements of low-energy solar neutrino fluxes ($^7$Be and $^{8}$B) will allow even better determination of $\theta_{12}$ [30]. The corrections due to $\theta_{13}$ will also be constrained better by LBL experiments as well as new multiple-baseline reactor anti-neutrino oscillation experiments [31].

It is useful to recall the cosmological bound. The combination of WMAP, 2dFGRS, and Lyman $\alpha$ data leads to an upper bound [32] (see [33] for a slightly weaker bound)

$$\sum_i m_{\nu_i} < 0.70 \text{ eV},$$

which translates to [34]

$$\langle |m_{ee}| \rangle < 0.23 \text{ eV},$$

allowing the maximum constructive interference between three mass eigenstates. This follows from the fact that neutrinos are degenerate in this mass range and the inequality

$$|U_{e1}^2 + U_{e2}^2 + U_{e3}^2| \leq |U_{e1}^2| + |U_{e2}^2| + |U_{e3}^2| = 1.$$  (9)

For a comparison [34], the reported evidence for the neutrinoless double beta decay suggest $\langle |m_{ee}| \rangle = (0.11-0.56) \text{ eV}$ [35], while the reanalysis in [14] gives 0.4-1.3 eV using a different set of nuclear matrix elements.

To summarize, we have obtained a robust lower bound on the effective electron-neutrino mass relevant to the neutrinoless double beta decay. For the degenerate and inverted mass spectra, the next generation experiments that have sensitivity on $\langle |m_{ee}| \rangle$ down to 0.01 eV can determine if neutrino is its own anti-particle. For the normal hierarchy, the effective electron-neutrino mass may even vanish. However, if the large-scale structure cosmological data, improved data on the tritium beta decay, or the long-baseline neutrino oscillation experiments establish the degenerate or inverted mass spectrum, the null result from such double-beta decay experiments will lead to a definitive result.

FIG. 3: Lower bound on $\langle |m_{ee}| \rangle$ vs confidence levels for the inverted hierarchy spectrum. Note that what is shown here is $\sqrt{\Delta m^2_{\text{atm}} \cos 2\theta_{12}}$, which is the minimum value of $\langle |m_{ee}| \rangle$ allowing the maximum cancellation between $m_1$ and $m_2$. The solid line is based on the atmospheric neutrino data before the update, while the dashed line with the update.

bounds are shown at different confidence levels in Fig. 3. One can see that

$$\langle |m_{ee}| \rangle > 0.013 \text{ (011) eV} \quad 95\% \text{ CL (99\% CL).}$$  (4)

The result is quite robust in the sense that one has to require an extremely high confidence level (99.7%) to bring $\langle |m_{ee}| \rangle$ below 0.01 eV. Recall that the proposed experiments are aiming at the sensitivity reaching $\langle |m_{ee}| \rangle \sim 0.01 \text{ eV}$ [13].

In all of the above discussions, we ignored $\theta_{13}$; First of all, $\theta_{13}$ is small due to the limit from CHOOZ reactor experiment [13]. Even setting the CHOOZ limit aside, it is well-known, however, that $\theta_{13}$ has very little effect on the determination of $\Delta m^2_{\text{atm}}$ [15], and also can only decrease the preferred values of $\theta_{12}$ [27, 36]. Therefore, the impact of a non-vanishing $\theta_{13}$ on $\Delta m^2_{\text{atm}}$ and $\theta_{12}$ can only strengthen our result.

One may also worry about corrections to the approximate formula Eq. (3) due to $\Delta m^2_{\text{sol}}$ and $\theta_{13}$. To minimize $\langle |m_{ee}| \rangle$, we can study the case where both $U^2_{e2}$ and $U^2_{e3}$ have the opposite sign from $U^2_{e1}$, giving

$$\langle |m_{ee}| \rangle = |(m_1 - m_3)c^2_{13} \cos 2\theta_{12} - (m_2 - m_1)c^2_{13} s^2_{12} + m_3(c^2_{13} \cos 2\theta_{12} - s^2_{13})|.$$  (5)

In the limit $\Delta m^2_{\text{sol}} = 0$ ($m_2 = m_1$) and $\theta_{13} = 0$, it reduces to Eq. (3) due to the first term above. The suppression factor due to $c_{13}$ is at most 4.4% (95% CL) thanks to the CHOOZ limit. The second term does not vanish due to $\Delta m^2_{\text{sol}} \neq 0$, and gives a correction at most of

$$\frac{\Delta m^2_{\text{sol}}}{2 \Delta m^2_{\text{atm}} \cos 2\theta_{12}} \lesssim 3\% \quad (95\% \text{ CL).}$$  (6)

Finally, the last term cannot be negative given the CHOOZ limit and only strengthens our limit. Overall, our lower bound can change at most by 8%.

[21] It is possible, however, that the leptogenesis occurs even with Dirac neutrinos [11].
[22] Other new physics beyond the Standard Model, e.g. R-parity violating supersymmetry, Majoron, double charged Higgs, etc can also cause neutrinoless double-beta decay (see e.g. [12] and references therein). However, such models induce Majorana mass for neutrinos from radiative corrections as well.
[23] The positive evidence for neutrino oscillation from the LSND experiment [13] does not fit into the standard three-generation framework. We ignore this evidence in this letter.
[24] The degenerate spectrum can further be either of normal or inverted hierarchy.
[25] This statement assumes that there are only three light neutrinos mass eigenstates. HM thanks Xerxes Tata on this point. See 22 for a related discussion.
