Title
Single SQUID frequency-domain multiplexer for large bolometer arrays

Abstract—We describe the development of a frequency-domain superconducting quantum interference device (SQUID) multiplexer which monitors a row of low-temperature sensors simultaneously with a single SQUID. Each sensor is ac biased with a unique frequency and all the sensor currents are added in a superconducting summing loop. A single SQUID measures the current in the summing loop, and the individual signals are locked-in detected after the room temperature SQUID electronics. The current in the summing loop is nulled by feedback to eliminate direct crosstalk. We have built an eight-channel prototype and demonstrated channel separation and signal recovery.

I. INTRODUCTION

Observations in the far-IR to mm wavelength region are opening a new window on the universe. For example, recent measurements of the cosmic microwave background anisotropy by BOOMERanG [1] and MAXIMA [2] lend strong support to inflationary cosmological models with a geometry close to flat. A new population of dusty luminous objects that may account for a significant fraction of all star formation is being explored by ground-based telescopes such as SCUBA/JCMT. Both of these types of observation have been possible only because of large steps in the sensitivity of bolometric receivers. In the future, further large steps in sensitivity will be possible by increasing the size of bolometer arrays. Large-format arrays of Voltage-biased Superconducting Bolometers (VSB) with SQUID readouts are being developed for this purpose [3].

If an individual readout circuit is used for each array element, a major limitation on the array size is the difficulty in implementing the large number of wires from the sensors to the cryogenic electronics and on to the room temperature. With a multiplexer, the number of wires can be greatly reduced. The large noise margin of the SQUID readout makes multiplexed readouts for large arrays possible. The NIST group is producing a time-domain multiplexer which has a SQUID switch for each sensor [4]. We are exploring multiplexing in the frequency-domain with a single SQUID per row of sensors. We have built an eight-channel prototype and demonstrated the channel separation and signal recovery.

II. MULTIPLEXER

The design of our multiplexer is schematically shown in Fig. 1. Each sensor is ac biased at a distinct frequency significantly above the rolloff frequency of the sensor and all the signals are inductively coupled to a superconducting summing loop. The SQUID measures the current in the summing loop via

Figure 1. Schematic of the eight-channel SQUID multiplexer. For test purposes, resistors $R_s=0.47\Omega$ are used to simulate the sensors being multiplexed, which is voltage biased by the bias resistors, $R_b=0.02\Omega$. 
a conventional coupling coil. Feedback from the SQUID output is used to null the total current in the summing loop, eliminating direct crosstalk between channels.

For an experimental evaluation of our multiplexing scheme, we have fabricated a prototype eight-channel multiplexer. The transformers are made by thin-film deposition and photolithography, which are suitable fabrication techniques for single-substrate integration with a large-format arrays of sensors. The inductances of the transformers are chosen to minimize the SQUID noise current at the multiplexer input. Details of the multiplexer fabrication and the SQUID noise current optimization procedures are reported elsewhere [5]. We used resistors $R_s=0.47 \Omega$ as mock sensors that are voltage-biased by the bias resistors, $R_b=0.02 \Omega$, and a commercial set of SQUID and readout electronics.

Fig. 2 shows the SQUID output measured with a spectrum analyzer with each resistor $R_s$ voltage-biased at frequencies ranging from $\sim2$kHz to $\sim10$kHz. The currents through the resistor $R_s$ are 20nA rms. All the bias frequencies are well resolved, and the mixing between bias frequencies is $\lesssim 0.05\%$. This demonstrates that the sensor currents can be monitored simultaneously with a single SQUID ammeter. The background noise is in good agreement with that predicted from Johnson noise, which is the quadrature sum of the contributions from all eight $R_s$ and shown by the dotted line.

In order to verify the signal recovery and to test for crosstalk between channels, we simultaneously amplitude modulate the bias voltage for channels 1 to 7 by 2% at frequencies ranging from 1.6Hz to 19Hz, and measure the SQUID output with a lock-in amplifier. Trace (a) in Fig. 3 is an example of the sensor signal recovery for channel 5, where the 5.06kHz bias voltage is amplitude modulated at 8.6Hz. As expected, a peak centered at 8.6Hz is observed. However, when the lock-in reference is obtained from the 9.66kHz bias of channel 8, which is not amplitude modulated, only the background noise appears as shown by trace (b). When the modulation is increased, a crosstalk $\lesssim 1\%$ is observed which may come from the drive electronics.

ACKNOWLEDGMENT

The authors are indebted to X. Meng for technical support in the device fabrication. The transformers were fabricated at the Berkeley Microfabrication Laboratory. This work was supported in part by the Director, Office of Science, Office of Basic Energy Sciences of the U.S. Department of Energy under Contract No. DE-AC03-76SF00098, by NSF Grant FD97-31200, and by NASA/Ames Grant FDNAG2-1398.
