Study of the Decay $\eta^0 \rightarrow \pi^+ \pi^- \gamma$

Frank S. Crawford, Jr. and LeRoy R. Price

Lawrence Radiation Laboratory
University of California
Berkeley, California

January 14, 1966

We present the results of a study of the decay process

$$\eta \rightarrow \pi^+ \pi^- \gamma.$$ \hfill (1)

The establishment of the existence of this decay mode of the eta, and a preliminary value for

$$R \equiv \frac{\Gamma (\eta \rightarrow \pi^+ \pi^- \gamma)}{\Gamma (\eta \rightarrow \pi^+ \pi^- \gamma)}$$

was given in an earlier paper.\(^1\)

Based on an almost background-free sample of 33 events of type (1), we obtain the following results:

1. The branching ratio is

$$R = 0.30 \pm 0.06;$$ \hfill (2)

Our result (2) is fairly consistent with those previously reported.\(^1^-4\)

2. The charge asymmetry is

$$f_+ - f_- = -0.02 \pm 0.17,$$ \hfill (3)

where $f_+$ is the fraction of events with $\pi^+$ more energetic than $\pi^-$ in the eta frame, and $f_- = 1 - f_+$. We conclude that reaction (1) exhibits no large violation of C invariance.\(^5\)

3. The angular distribution of the dipion shows that the dipion has $J = 1$. Other values for $J$ are strongly rejected.

4. The assumption that the rho meson dominates the decay mode gives a
good fit to the gamma ray energy distribution ($\chi^2$ probability of 40%), whereas the assumption of a nonresonant $J = 1$ dipion fits rather poorly ($\chi^2$ probability of 4%).

5. We find no evidence for the enhancement at low gamma-ray energy reported by Pauli and Muller. 6

The remainder of the paper is devoted to experimental details and a more detailed discussion of the results. Our initial sample of events consists of about 4000 four-pronged events produced by 1170-MeV/c $\pi^+$ in the Alvarez 72-in. hydrogen bubble chamber. Protons are identified on the scanning table on the basis of their bubble density. All events are fit to a number of hypotheses (described below), and then a series of cut-offs is applied. The effects of the cutoffs is estimated using the Monte Carlo program FAKE. 7 The cutoffs are as follows:

A. **Four-constraint (4C) fit.** If $\chi^2$ for the reaction

$$\pi^+ p \rightarrow \pi^+ p^+ p^-$$

is less than 35, we reject the event. 8

B. **$\pi^+ \pi^- \pi^0$ production.** The events are fit (1C) to the reaction

$$\pi^+ p \rightarrow \pi^+ p \pi^+ \pi^- \pi^0$$

and are removed if $\chi^2$ is less than 7.

C. **$\pi^+ \pi^- \gamma$ production.** If $\chi^2$ for the fit (1C) to

$$\pi^+ p \rightarrow \pi^+ p \pi^+ \pi^- \gamma$$

is greater than 8.6, the event is discarded. We also demand that this $\chi^2$ be less than that for reaction (5).

D. **Coulomb scatter.** One of the four final tracks is deleted, and the remaining tracks are then fit (1C) to reaction (4). Events for which $\chi^2$ is less than $\chi^2$ for reaction (6) are removed, provided that $\psi p \beta$ is less...
than 35 rad-MeV/c, where $\psi$ is the space angle between the fitted and measured momentum vector of the deleted track, and $p$ is the fitted momentum of this track. This cutoff removes 12 events, of which $1.7 \pm 0.3$ are good eta decays, according to FAKE.

E. Scanning-table examination. The remaining events are examined on the scanning table to search for possible electrons misfit as pions. Two events involve Dalitz-pair electrons and are removed.

We are left with 38 good events of type (6). These are fit (2C) to

$$
\pi^+ p \rightarrow \pi^+ n \eta, \quad \eta \rightarrow \pi^+ \pi^- \gamma,$$

using an eta mass of 548. Their $\chi^2$ distribution agrees well with the theoretical $\chi^2$ (2C) distribution up to $\chi^2$ about 20. Five events have large $\chi^2$ (2C) and are believed to be type (6), but not from eta decay (7). We take the 33 events with $\chi^2$ (2C) less than 20 as our final sample. In Table I we give details of the 33 events.

From the same sample of 4000 four-pronged events, using a similar method of analysis, we find 113 good events of the type

$$
\pi^+ p \rightarrow \pi^+ n \eta, \quad \eta \rightarrow \pi^+ \pi^- 0.$$

To illustrate the clean separation between $\pi^+ \pi^- 0$ and $\pi^+ \pi^- \gamma$ production, we show in Fig. 1a a plot of the unfit missing-neutral mass (squared) recoiling against the $\pi^+ p \pi^+ \pi^-$ for our 33 + 5 + 113 events. To illustrate the lack of non-eta background for $\pi^+ \pi^- \gamma$ production we show in Fig. 1b a plot of $m^2(\pi^+ \pi^- \gamma)$, using the final $\pi^+$ that gives a mass closest to the eta, for our 38 events of type (6). We see that our selection criteria based on $\chi^2$ give essentially the same sample that we would obtain if we selected on missing-neutral mass and on $m(\pi^+ \pi^- \gamma)$. The $\chi^2$ method carries less visual appeal than the mass plots, but has the advan-
tages that it takes the measurement errors into account systematically, and that it is easier to calculate (using FAKE) the effects of cutoffs based on $\chi^2$ than of cutoffs based on calculated errors in missing mass. \footnote{1} We now turn to the results.

**Angular distribution.** In Fig. 2 we plot the (folded) angular distribution in $|\cos \theta|$, where $\theta$ is the angle between the $\pi^+$ and $\gamma$ in the dipion c.m. system. From FAKE we find that our detection efficiency is essentially independent of $\cos \theta$. Angular-momentum conservation and zero eta spin demand that the dipion have $J_z = \pm 1$ for $z$ along the gamma direction in the dipion frame. Thus for a pure dipion state $J$, the distribution in $\cos \theta$ is given by $|Y_J^{\pm 1}|^2$. Normalizing to 33 counts and calculating $\chi^2$ for curves corresponding to $J = 1, 2,$ and $3$, we find $\chi^2 = 4.5$ for $J = 1$, 49.4 for $J = 2$, and 102.0 for $J = 3$; in each case the "expected" $\chi^2$ is 4. We conclude that the dipion is dominated by $J = 1$. The dominant decay amplitude is therefore C-conserving (i.e., has odd $J$), \footnote{14} and the dipion has the spin and $I$-spin of the rho meson.

**Charge asymmetry.** If there is a small amount of C-nonconserving amplitude, we may have some $J = 2$ (or other even value) amplitude present. The interference between the dominant $J = 1$ and any even $J$ leads to odd powers of $\cos \theta$ in the angular distribution, or, equivalently, to a charge asymmetry $f_+ - f_- \neq 0$ in the pion-energy distribution in the eta rest frame. \footnote{5} Since we have 17 events with $\cos \theta > 0$ and 16 with $\cos \theta < 0$, the raw data give $f_+ - f_- = -(1/33) \pm 0.17$. Using FAKE we find that the choice of the wrong $\pi^+$ in a small fraction of the events leads to a small spurious asymmetry. Correcting for this, we find the result given in Eq. (3).
Energy spectrum of the gamma ray. In Fig. 3 we plot the distribution of the energy $p$ of the gamma ray in the eta rest frame, for the 33 events. We have no cutoff on gamma-ray energy. The detection efficiency $\epsilon(p)$ depends on the gamma energy and on our $\chi^2$ cutoffs; it is calculated using FAKE,\textsuperscript{12} and plotted in Fig. 3. We multiply any theoretical curve by $\epsilon(p)$ before fitting to the data.

The simplest matrix element corresponding to a dipion with $J = 1$ is

$$|M|^2 = p^2 q^2 \sin^2 \theta,$$

where $q$ is the momentum of either pion in the dipion frame, and $p$ and $\theta$ are as previously defined. We have already verified in Fig. 2 that the angular distribution fits $\sin^2 \theta$. We therefore integrate over $\cos \theta$ and write

$$dN = C \epsilon(p) p^2 q^2 \, dp,$$

where $C$ is a normalization constant, and $dN$ is the number of counts expected in the interval $dp$, taking into account the detection efficiency.

This "nonresonant $J = 1$" curve is normalized to 33 events in Fig. 3 and gives $\chi^2 = 13.2$ with 6 degrees of freedom for a $\chi^2$ probability of 4%, a rather poor fit.

Next we assume that the $I = 1$, $J = 1$ dipion phase shifts are dominated by the rho meson.\textsuperscript{13} We then replace the factor $q^2$ in Eq. (10) by a resonance factor:\textsuperscript{14}

$$q^2 \to \frac{m_{\pi\pi}}{q} \cdot \frac{\Gamma}{(m^2_{\rho} - m^2_{\pi\pi})^2 + m^2_{\rho} \Gamma^2},$$

where $\Gamma = (q^2/q_0^2)\gamma$, $m_{\pi\pi}$ is the mass of the dipion, $m_{\rho}$ is the rho mass (765 MeV), $q_0$ is the value of $q$ at resonance (357 MeV), and
$\gamma$ is the "reduced width" of the $\rho$ (124 MeV). This "rho-dominant" curve is normalized to 33 events in Fig. 3 and gives $\chi^2 = 5.9$ for a $\chi^2$ probability of 40%, a good fit. Thus we lend some support to the rho-dominant model. (However, it is apparent from Fig. 3 that any other model that shifts the spectrum towards lower gamma-ray energies would also fit.)

The fact that we find evidence for final-state interactions in the dipion system lends encouragement to the possibility of (eventually) detecting the charge asymmetry, if a small amount of $C$-violating amplitude is actually present; if there were no final-state interactions, the interference term would necessarily vanish (by CPT invariance) and there could then be no charge asymmetry even if $C$ were violated. 15

Branching ratio. Using the detection efficiency $\epsilon(p)$ and the "rho-dominant" curve, we calculate 16 that our total corrected number of decays

$$\eta \rightarrow \pi^+ \pi^- \gamma$$

is $40.2 \pm 7.1$. We calculate using FAKE that this includes

$2.2 \pm 0.5$ events of type (8) that were not removed by the cutoffs. All other corrections are negligible. 17

We also calculate from our 113 good events of type (8) a corrected number

$128.0 \pm 11.3$. We thus find

$$R = (40.2 - 2.2)/128 = 0.30 \pm 0.06.$$  This is consistent with the prediction of the rho-dominant model. 18

Low-energy gamma rays.—Pauli and Muller 6 find about as many

$$\eta \rightarrow \pi^+ \pi^- \gamma$$

decays with gamma energy between 10 and 60 MeV in the eta frame as they do between 60 and the maximum allowed value of 203 MeV; namely, they find about 12 events above estimated background in each of the two regions. If the "true" spectrum (corresponding to 100% detection efficiency) gave equal numbers of counts in these two regions, then, taking
into account our detection efficiency $\epsilon(p)$ as plotted in Fig. 3, we would expect to find 20 counts below 60 MeV, whereas we find none. (For our best-fit curve in Fig. 3 we expect two counts below 60 MeV and find none; this is an entirely reasonable statistical fluctuation.) We conclude that there are no anomalous low-energy gamma rays. ¹⁹

We are grateful to Earle C. Fowler, Ronald A. Grossman, and L. J. Lloyd for their contributions to the data analysis, and to Luis W. Alvarez for his interest and support.
FOOTNOTES AND REFERENCES

† Work sponsored by the U. S. Atomic Energy Commission.

2. Margaret C. Foster, University of Wisconsin, Ph.D. thesis, 1965 (unpublished) finds $R = 0.20 \pm 0.04$.

3. H. W. J. Foelsche and H. L. Kraybill, Phys. Rev. 134, B1138 (1964) find $R = 0.14 \pm 0.08$.

4. E. Pauli and A. Muller, Phys. Letters 13, 351 (1964) would find $R = 0.27 \pm 0.10$ if they used only their "Class a" events, which involve unambiguous gamma rays. [When they include "Class b" events (Ref. 6), they find $R = 0.73 \pm 0.25$.]

5. The possibility of small violations of $C$ invariance with $f_+ - f_-$ perhaps of order 0.1 has been suggested by J. Bernstein, G. Feinberg, and T. D. Lee, Phys. Rev. 139, B1650 (1965), and by S. L. Glashow and C. M. Sommerfield, Phys. Rev. Letters 15, 78 (1965).

6. E. Pauli and A. Muller, Ref. 4, and E. Pauli, University of Strasbourg, Ph.D. thesis, 1965 (unpublished) find an enhancement at gamma energies between 10 and 60 MeV in the eta frame. The enhancement arises from their "Class b" events, which are kinematically ambiguous with a zero-energy gamma ray, i.e. with no gamma ray at all. Their Class b peak at the eta mass band amounts to about 2.7 standard deviations above their non-eta background. (See also footnote 19.)

8. Experience has shown that, for a correct hypothesis, the $\chi^2$ distributions for 72-in. chamber events agree with the theoretical distributions for the appropriate constraint class, provided the theoretical values of $\chi^2$ are multiplied by 2. Thus the 4C cutoff at $\chi^2 = 35$ corresponds to a theoretical $\chi^2$ of approximately 18. Our 4C cutoff causes our detection efficiency for gamma rays to be negligibly small below a laboratory gamma energy of about 20 MeV. We make no cutoff on gamma-ray energy.

9. We reject events with $\chi^2(4C) < 35$, and then demand $\chi^2(1C) < 8.6$ for reaction (5), $\chi^2(2C) < 6$ for reaction (8), and $\chi^2(2C)$ for (8) less than that for (7).

10. We define $\chi^2 = \Sigma \left( \left( N_i - \bar{N}_i \right)^2 / \bar{N}_i \right)$, where $N_i$ is the observed number of counts in the $i$th bin, and $\bar{N}_i$ is the expected number from the smooth theoretical curve. The smooth curve is normalized to the observed 33 counts, and there are then no free parameters.

11. The eta and gamma have $C = +1$ and $-1$, respectively. Thus $C$ conservation demands $C(\pi^+\pi^-) = -1$. But $C(\pi^+\pi^-)$ equals $(-1)^J$; therefore $J$ is odd. Thus if we had found $J = 2$ dominant for the dipion, it would have indicated a gross violation of $C$ conservation.

12. We start with a large number of simulated events of type (7). The momentum distribution of the etas and of the other final particles is taken to be that observed in our larger sample of etas that decay via mode (8). The simulated events are analyzed by the same kinematics programs and subjected to the same cutoffs as those used for the real candidates.

15. J. Bernstein et al., Ref. 5.

16. We divide our 33 events by the average detection efficiency $\bar{\epsilon}$, where $\bar{\epsilon} = \int \epsilon(p) (dN/dp)dp / \int (dN/dp)dp$, where the integral extends over the entire range $p = 0$ to 203 MeV. If $dN/dp$ is given by the rho-dominant curve we find $\bar{\epsilon} = 0.821$. The nonresonant spectrum (10) would give $\bar{\epsilon} = 0.820$, and thus the same branching ratio $R$.

17. For example, we estimate that our 33 events include less than 0.1 events of type (4).

18. M. Gell-Mann et al. (Ref. 13) predict $r = \Gamma(\eta \to \pi^+\pi^-\gamma)/\Gamma(\eta \to \gamma\gamma) = \frac{1}{2} (\gamma^2_{\rho \pi \pi}/4\pi)^2 (\gamma^2_{\rho \pi \pi}/4\pi) (9/4) \approx 0.28$, for $\gamma^2_{\rho \pi \pi}/4\pi \approx \gamma^2_{\rho \pi \pi}/4\pi \approx \frac{1}{2}$. If we take $\Gamma(\eta \to \gamma\gamma)/\Gamma(\eta \to \text{charged}) \approx 1.26$, from A. H. Rosenfeld, A. Barbaro-Galtieri, W. H. Barkas, P. L. Bastien, J. Kirz, and M. Roos, Rev. Mod. Phys. 37, 633 (1965), then our result (2) gives $r \approx 0.18$.

19. In this experiment we would not detect a low-energy gamma ray peak if it lay below 20 MeV in the eta frame. Neither would we detect the decay $\eta \to \pi^+\pi^-$, which is forbidden by parity conservation. Neither nearly would we detect $\zeta(560) \to \pi^+\pi^-$, which would be indistinguishable from $\eta(548) \to \pi^+\pi^-$, and is forbidden only by the fact that the $\zeta(560)$ apparently does not exist. All of these possible processes would (if they occurred) be included in the Class b events of Pauli and Muller. 6
Table I. Details of 33 events. $\theta$ is the angle between the $\pi^+$ and $\gamma$ in the dipion rest frame; $p$ is the $\gamma$ energy in the eta frame.

FIGURE LEGENDS

Fig. 1. Mass distributions. (a) Distribution in $m^2$ (mass-squared) of the missing neutral in $\pi^+p \rightarrow \pi^+ p \pi^+ \pi^- + \text{neutral}$. All events with $m^2$ less than 0.006 (BeV/c$^2$)$^2$ also happen to satisfy our $\chi^2(1C)$ criteria for selecting gamma rays. The five shaded gamma rays do not come from eta decay. (b) Distribution in $m^2$ of $\pi^+ \pi^- \gamma$ for $\pi^+ p \rightarrow \pi^+ p \pi^+ \pi^- \gamma$. (That $\pi^+$ is chosen which gives $m(\pi^+ \pi^- \gamma)$ closest to the eta mass 548 MeV.) The five shaded gamma rays do not satisfy our $\chi^2(2C)$ criteria for $\eta \rightarrow \pi^+ \pi^- \gamma$. The three "good-eta gamma rays" that lie outside the main eta peak do satisfy our $\chi^2$ criteria and are used. (According to our FAKE calculation, the sample contains an estimated 2.2 spurious gammas arising from neutral pions with large measurement errors.)

Fig. 2. Angular distribution for $\eta \rightarrow \pi^+ \pi^- \gamma$. Here $\theta$ is the angle between the $\pi^+$ and the $\gamma$ in the dipion rest frame. The three smooth curves correspond to $J = 1$, 2, and 3 for the dipion. ($J = 0$ is forbidden by angular-momentum conservation, since the eta spin is zero.) We see that $J = 1$ fits well, and $J = 2$ and 3 fit poorly.

Fig. 3. Energy distribution. The detection efficiency $\epsilon(p)$ is calculated using FAKE. The two theoretical curves correspond to a nonresonant $J = 1$ and to a rho-dominant $J = 1$ dipion. Neither curve has any free parameter except for a normalization constant. The curves are multiplied by $\epsilon(p)$ before plotting and comparing with the data. The rho-dominant model fits very well, the nonresonant model not so well.
