ABSTRACT
We introduce massive black holes (BHs) in the Feedback In Realistic Environments project and perform high-resolution cosmological hydrodynamic simulations of quasar-mass halos ($M_{\text{halo}}(z = 2) \approx 10^{12.5} M_\odot$) down to $z = 1$. These simulations model stellar feedback by supernovae, stellar winds, and radiation, and BH growth using a gravitational torque-based prescription tied to resolved properties of galactic nuclei. We do not include BH feedback. We show that early BH growth occurs through short ($\lesssim 1$ Myr) accretion episodes that can reach or even exceed the Eddington rate. In this regime, BH growth is limited by bursty stellar feedback continuously evacuating gas from galactic nuclei, and BHs remain under-massive relative to the local $M_{\text{BH}} - M_{\text{bulge}}$ relation. BH growth is more efficient at later times, when the nuclear stellar potential retains a significant gas reservoir, star formation becomes less bursty, and galaxies settle into a more ordered state, with BHs rapidly converging onto the scaling relation when the host reaches $M_{\text{bulge}} \sim 10^{10} M_\odot$. Our results are not sensitive to the details of the accretion model so long as BH growth is tied to the gas content within $\sim 100$ pc of the BH. Our simulations imply that bursty stellar feedback has strong implications for BH and AGN demographics, especially in the early Universe and for low-mass galaxies.

Key words: galaxies: formation — galaxies: evolution — galaxies: active — quasars: supermassive black holes — black hole physics — cosmology: theory

1 INTRODUCTION
The observed connection between galaxies and central massive black holes (BHs; e.g. Kormendy & Ho 2013; Heckman & Best 2014) poses significant challenges for galaxy formation models. Correlations between dynamical BH mass measurements and host galaxy properties in the local universe (e.g. Häring & Rix 2004; Sánchez et al. 2016) have been interpreted as (1) a non-causal consequence of hierarchical merging (Peng 2007; Hirschmann et al. 2010; Jahnke & Macciò 2011), (2) the causal signature of self-regulation by BH feedback (e.g. Silk & Rees 1998; Murray et al. 2005; Di Matteo et al. 2005; Hopkins et al. 2007), or (3) the result of a common gas supply for star formation and BH growth, regulated by gravitational torques (e.g. Kauffmann & Heckman 2009; Chen et al. 2013; Anglés-Alcázar et al. 2013, 2015, 2017). Understanding nuclear fueling in a cosmological context is a crucial step towards uncovering the nature of BH–galaxy co-evolution.

The Feedback In Realistic Environments (FIRE) cosmological “zoom-in” simulations1 (Hopkins et al. 2014, 2017) offer an ideal setting to investigate the evolution of massive BHs. By implementing stellar feedback processes on the scale of star-forming regions directly following stellar population synthesis models, the FIRE simulations reproduce a variety of galaxy (Hopkins et al. 2014; Feldmann et al. 2017; Ma et al. 2016) and CGM (Faucher-Giguère et al. 2015, 2016; Muratov et al. 2015; Hafen et al. 2017) observables. Here, we use high-resolution cosmological hydrodynamic simulations of quasar-mass halos ($M_{\text{halo}} \approx 10^{12.5} M_\odot$ at $z \approx 2$; e.g. White et al. 2012) from early times down to $z = 1$ to study the impact of stellar feedback on massive BH growth.

Our simulations model the inhomogeneous, dynamic interstellar medium in the nuclear regions of galaxies (≤ 100 pc) while self-consistently capturing mass transport from cosmological gas infall down to galactic nuclei (Fig. 1, top right). We rely on results from nuclear-scale simulations (Hopkins & Quataert 2010, 2011; Hopkins et al. 2016) to estimate the feeding rate of the BH accretion.

disk based on resolved galaxy properties on scales ⩽ 100 pc. Specifically, we model the inflow rate driven by gravitational torques induced by non-axisymmetric perturbations in the stellar potential.

2 SIMULATIONS

We use the N-body+hydrodynamics code GIZMO\(^2\) (Hopkins 2015) to re-simulate four halos from the A series of MassiveFIRE galaxies presented in Feldmann et al. (2017), which did not include BH physics. This set of simulations covers a range of halo formation histories for halo mass \(M_{\text{halo}} \approx 10^{12.5}\,M_\odot\) at \(z = 2\). Our new simulations use the updated FIRE-2 code (Hopkins et al. 2017), including the meshless finite mass (MFM) hydrodynamics solver and improvements to the accuracy of stellar feedback coupling algorithms, described therein. We assume a standard ΛCDM cosmology consistent with observational constraints (e.g. Planck Collaboration et al. 2016) and evolve halos down to \(z = 1\) with baryonic and dark matter particle masses \(m_b = 3.3 \times 10^4\,M_\odot\) and \(m_{DM} = 1.7 \times 10^5\,M_\odot\) and force softening \(\epsilon = 0.7\,\text{pc}, \epsilon_b = 7\,\text{pc},\) \(\epsilon_{\text{BH}} = 7\,\text{pc},\) and \(\epsilon_{\text{DM}} = 57\,\text{pc},\) where \(\epsilon_{\text{gas}}\) is the minimum adaptive force softening for gas (identical to the kernel smoothing scale) and \(\epsilon_b, \epsilon_{\text{BH}}, \) and \(\epsilon_{\text{DM}}\) are fixed in physical units at \(z < 9\). Additionally, we use the Milky Way-mass galaxy m12i from the FIRE-2 Latte simulation suite (Wetzel et al. 2016) at three different resolution levels (\(m_b = [7, 56, 450] \times 10^4\,M_\odot\)) for numerical convergence tests (these runs do not include BHs).

We treat BHs as individual collisionless particles that grow through accretion and mergers (Springel et al. 2005). We model accretion as \(M_{\text{BH}} = (1 - \eta) M_{\text{Torque}},\) where \(\eta = 0.1, M_{\text{Torque}} \propto e_T \int_0^{r_0/2} M_b R^3 \, \dot{M}_b \, dR,\) and \(\dot{M}_b\) and \(M_b\) are the mass fraction and total mass of the disk (stars and gas) within a radial aperture \(R_0\) enclosing 256 gas elements. An upper limit of 140 pc (physical) is imposed on \(R_0\) to avoid accreting distant gas. The \(e_T\) pre-factor encapsulates uncertainties in processes that affect gas transport on unresolved scales (e.g. BH feedback). We set \(e_T = 2.5\) to match the observed normalization of the \(M_{\text{BH}}-M_{\text{bulge}}\) relation at late times but \(e_T\) could in principle vary in different regimes. We refer to Anglés-Alcázar et al. (2017) for details of the numerical implementation, including the on-the-fly bulge-disk decomposition. BHs can exceed the Eddington rate \(M_{\text{edd}}\) by up to a factor of 10, consistent with recent simulations of

Figure 1. Left: Evolution of the most massive BH in simulation A2 (a representative example). We show, from top to bottom: (1) BH mass, (2) accretion rate, (3) Eddington ratio, (4) gas/stellar mass surface density within the variable accretion radius \(R_0 \leq 100\,\text{pc}\), and (5) the 90th percentile radial velocity of outflowing gas within 1 kpc (\(v_{\text{ap}}\)) compared to the escape velocity at 1 kpc (\(v_{\text{esc}}\)). The top two panels also indicate the total stellar mass and SFR of the host galaxy. Top right: Projected mass-weighted gas temperature maps at \(z = 2.3\) on different scales centered on the main BH. The white dashed line indicates \(R_{\text{vir}}\) (left) and the black circle (right) corresponds to the central 100 pc. Bottom right: Projected gas surface density (from purple to red) overlaid on top of the stellar mass surface density (background gray scale); we show redshift evolution from \(z = 6 \rightarrow 1\). The white circles indicate the central 100 pc. Length scales indicated on the panels are in physical units. At early times, \(\Sigma_{\text{gas}}\) fluctuates by more than three orders of magnitude owing to stellar feedback evacuating gas within the accretion radius; \(M_{\text{BH}}\) can reach the Eddington rate but only intermittently during \(\leq 1\,\text{Myr}\) phases. More sustained BH growth begins at \(z \approx 4\), when the stars dominate the gravitational potential and the nuclear gas content becomes more steady.
super-Eddington accretion (e.g. Jiang et al. 2014). Our results are largely insensitive to this limit (§3.3).

We introduce one BH seed with mass \( M_{\text{seed}} = 1.4 \times 10^4 \, M_\odot \) at the location of the most bound star particle in halos with stellar mass \( M^{\text{bol}}_* > 1000 \times M_{\text{seed}} \) using a friends-of-friends algorithm (e.g. Di Matteo et al. 2008). BH orbits are affected by dynamical friction, which would be underestimated owing to finite mass resolution. In order to more physically model BH dynamics, each BH is given an initial "dynamical mass" \( m_{BH} = 300 \times m_\bullet = 60 \times m_{DM} \) independent of the physical \( M_{BH} \) set by accretion. Once \( M_{BH} \) reaches \( \sim m_{BH} \), both remain equal for the rest of the simulation. BH feedback is intentionally disabled to allow for a clean exploration of the impact of stellar feedback on BH growth. BH properties are saved at every time-step, yielding a time resolution in \( M_{BH} \) of up to \( 10^3 \, \text{yr} \).

3 RESULTS

3.1 Representative black hole accretion history

Fig. 1 (left) shows the growth histories of the main galaxy in simulation A2 and its central BH. At early times, A2 experiences intense bursts of star formation, growing from \( M_* \sim 10^7 \rightarrow 10^{10} \, M_\odot \) in the redshift range \( z = 10 \rightarrow 4 \). During this early period, the total star formation rate (SFR) can reach \( M_* \sim 10 \rightarrow 4 \times 10^6 \, M_\odot \, \text{yr}^{-1} \). Stellar feedback drives large scale winds with 90th-percentile velocity \( v_{90} \sim 10^2 \, \text{km} \, \text{s}^{-1} \) (within 1 kpc), evacuating a large fraction of ISM gas and temporarily shutting down star formation (Mayer et al. 2015; Anglés-Alcázar et al. 2016). Feedback-driven outflows/inflows cause significant radial stellar migration seen as fluctuations in \( \Sigma \), (El-Badry et al. 2016). As the galaxy grows to \( M_* > 10^{10} \, M_\odot \), star formation becomes less bursty and rapid outflow events become less frequent (e.g. Ma et al. 2017a). Sustained star formation at rates \( M_* \sim 100 \, M_\odot \, \text{yr}^{-1} \) grows the stellar mass to \( M_* = 4 \times 10^{11} \, M_\odot \) by \( z = 1 \) while maintaining a substantial nuclear gas reservoir (\( \Sigma_{\text{gas}} \sim 10^2 \, M_\odot \, \text{kpc}^{-2} \)).

Despite the rapid growth of the host galaxy, the central BH grows by less than one order of magnitude by \( z = 4 \). Early BH growth occurs through sporadic accretion episodes, reaching \( M_{BH} \sim 0.01 \, M_\odot \, \text{yr}^{-1} \) when the nuclear gas surface density peaks at \( \Sigma_{\text{gas}} \sim 10^2 \, M_\odot \, \text{kpc}^{-2} \). BH accretion can reach or even exceed the Eddington rate during short phases (\( \lesssim 1 \, \text{Myr} \)), but the total mass accumulated is limited by the availability of gas to accrete over longer timescales. At early times, \( \Sigma_{\text{gas}} \) fluctuates by more than three orders of magnitude owing to bursty stellar feedback evacuating gas from the nucleus for \( \sim 10 \rightarrow 100 \, \text{Myr} \) intervals (e.g. Torrey et al. 2017). Efficient BH growth requires a sustained nuclear gas reservoir, only achieved at \( z < 4 \) when the stellar component dominates the gravitational potential and gas is more effectively retained in the nucleus (in other simulated halos, efficient BH growth can be delayed until \( z \sim 2 \)). Thumbnails in Fig. 1 (bottom right) show the evolution of the gas and stellar components in the central 2 kpc from \( z = 6 \rightarrow 1 \), illustrating the transition from (1) the irregular morphology, bursty star formation, and highly dynamic conditions prevalent at early times to (2) the well-defined stellar potential, more steady star formation, and long-lived nuclear gas disk enabling sustained BH growth at later times.

We find \( M_{BH} \sim 0.1 \, M_\odot \, \text{yr}^{-1} \) frequently at \( z < 4 \), corresponding to a bolometric luminosity \( L_{\text{bol}} \sim 6 \times 10^{44} \, \text{erg} \, \text{s}^{-1} \) (for a 10% radiative efficiency), while rare accretion episodes can reach \( M_{BH} \sim 1 \, M_\odot \, \text{yr}^{-1} \). Our simulations thus predict that moderate luminosity active galactic nuclei (AGN) at high redshift can be stochastically fueled and do not require major mergers events, in agreement with observations (e.g. Kocevski et al. 2012). The gas accreted

![Figure 2](image-url)
...in good agreement with Fig. 2, while larger apertures overestimate \( M_{\text{BH}} \) but be higher than predicted by our fiducial gravitational torque model (e.g. Anglés-Alcázar et al. 2015). In recent simulations based on Bondi-like accretion and parameterized star formation-driven kinetic winds (Costa et al. 2014) or delayed cooling thermal supernova feedback (Dubois et al. 2015; Bonoli et al. 2016; Bower et al. 2017; Habouzit et al. 2017; Prieto et al. 2017) also find suppressed \( M_{\text{BH}} \) in low-mass galaxies, in qualitative agreement with our results. We find that the early suppression of BH growth by stellar feedback is generic to models in which \( M_{\text{BH}} \) is tied to the nuclear gas content, provided that the effects of stellar feedback in the nucleus are resolved. Simulations that model \( M_{\text{BH}} \) based on the larger-scale (\( \sim 500 \) pc) galactic gas reservoir can greatly overestimate early BH growth. We note, however, that Bondi accretion may inhibit the growth of low-mass BHs even in the presence of a continuous gas supply owing to the strong dependence on BH mass, \( M_{\text{BH}} \propto M_{\text{BH}}^2 \) (e.g. Anglés-Alcázar et al. 2015). In our simulations, most of the gas in the central \( \sim 100 \) pc is cold and rotationally supported when BHs grow efficiently, which justifies the use of the gravitational torque model. Nonetheless, \( M_{\text{BH}} \) could be higher than predicted by our fiducial gravitational torque model at early times. For sufficiently high accretion efficiency per free-fall time (\( \alpha > 1\% \)), there would be enough gas in early nuclei to rapidly grow BHs to the local \( M_{\text{BH}} \sim M_{\text{M•}} \) relation.

Our fiducial simulations predict under-massive BHs in low-mass galaxies, in agreement with observations of the local \( M_{\text{BH}} \sim M_{\text{bulge}} \) relation (e.g. Graham & Scott 2013; Savorgnan et al. 2016), and substantial scatter in \( M_{\text{BH}} \) at \( M_{\text{bulge}} \sim 10^{10} M_\odot \) owing to rapid convergence onto the scaling relation once BHs start growing efficiently. In future work, it will be interesting to more systematically investigate the implications of stellar feedback for the growth of \( z > 6 \) quasars (e.g. Mortlock et al. 2011), over-massive relic BHs (e.g. McConnell et al. 2011), and \( M_{\text{BH}} \) measurements in active dwarfs (e.g. Jiang et al. 2011; Reines et al. 2013). The transition in BH fueling mode driven by stellar feedback also has direct implica-

![Figure 3. Top panels: Evolutionary tracks in the \( M_{\text{BH}}-M_{\text{bulge}} \) plane averaged over our four quasar-mass halos, where we compute BH growth in post-processing as \( M_{\text{BH}} = M_{\text{BH}}(R_0)/500 \) for the SFR within different apertures \( R_0 = 100\) pc–1 kpc (left), and \( M_{\text{BH}} = \alpha M_{\text{gas}}/t_{\text{dyn}} \) for different \( \alpha \) values, where \( t_{\text{dyn}} \approx (R/R_{\text{cm}})^{1.2} \) and \( M_{\text{tot}} \) is the total mass within \( R_0 = 100\) pc (right). Bottom panels: Convergence tests for galaxy m12i at three resolution levels, where we compute \( M_{\text{BH}} = (1 - \alpha) \times M_{\text{torque}} \) for different \( R_0 \) (left) and \( M_{\text{BH}} = \alpha M_{\text{gas}}/t_{\text{dyn}} \) for \( R_0 = 100\) pc and different \( \alpha \) values (right). We limit accretion to \( M_{\text{BH}} \leq 10 M_{\text{edd}} \) in all cases, except in the right top right panel where we also show \( M_{\text{BH}} \leq M_{\text{edd}} \) (dotted lines). The gray shaded area shows the Häring & Rix (2004) relation. Stellar feedback limits early BH growth when \( M_{\text{BH}} \) is tied to the gas content within \( \sim 100\) pc, but \( M_{\text{BH}} \) could be high enough to grow early massive BHs more quickly than in our fiducial calculations if \( \alpha \) is temporarily elevated.]
