Parents have large genetic and environmental influences on offspring’s cognition, behavior, and brain. These intergenerational effects are observed in mood disorders, with particularly robust association in depression between mothers and daughters. No studies have thus far examined the neural bases of these intergenerational effects in humans. Corticolimbic circuitry is known to be highly relevant in a wide range of processes, including mood regulation and depression. These findings suggest that corticolimbic circuitry may also show matrilineal transmission patterns. Therefore, we examined human parent–offspring association in this neurocircuitry and investigated the degree of association in gray matter volume between parent and offspring. We used voxelwise correlation analysis in a total of 35 healthy families, consisting of parents and their biological offspring. We found positive associations of regional gray matter volume in the corticolimbic circuit, including the amygdala, hippocampus, anterior cingulate cortex, and ventromedial prefrontal cortex between biological mothers and daughters. This association was significantly greater than mother–son, father–daughter, and father–son associations. The current study suggests that the corticolimbic circuitry, which has been implicated in mood regulation, shows a matrilineal-specific transmission patterns. Our preliminary findings are consistent with what has been found behaviorally in depression and may have clinical implications for disorders known to have dysfunction in mood regulation such as depression. Studies such as ours will likely bridge animal work examining gene expression in the brains and clinical symptom-based observations and provide promising ways to investigate intergenerational transmission patterns in the human brain.

Key words: anxiety disorder; MRI; intergenerational imaging

Introduction

Parents have large genetic and environmental influences on offspring’s cognition, behavior, and brain (Curley and Mashoodh, 2010; Cabrera et al., 2011; Curley, 2011). Furthermore, intergenerational trait transmission is often observed in the psychopathology of major psychiatric conditions, such as mood disorders.
The purpose of the current study was to examine female-specific intergenerational transmission patterns on brain structure in parent–offspring pairs in healthy individuals. We hypothesized that mother–daughter pairs would reveal significantly positive gray matter volume (GMV) associations in the corticolimbic brain regions (implicated in mood disorders) compared with other parent–offspring pairs. Our hypothesis was based on findings from previous studies demonstrating that depression exhibits strong female-specific intergenerational transmission patterns indicated above (Fergusson et al., 1995; Goodman and Gotlib, 1999; Goodman, 2007; Piche et al., 2011). Therefore, we focused on corticolimbic circuitry, including the amygdala, hippocampus, ACC, and vmPFC GMV, and analyzed the degree of association between mothers and daughters compared with mothers and sons, fathers and sons, and fathers and daughters, in these brain regions.

Materials and Methods

Participants. A total of 35 healthy families, consisting of parents aged 33–48 years and their biological offspring aged 5–13 years, were included for the present study from a larger study that was not focused on the corticolimbic system and related behavior. Participants were recruited from local newspapers, school mailings, flyers, and mother’s clubs. Exclusion criteria for this study were the presence of neurological or psychiatric disorders, including substance abuse, the use of medication, and/or contraindication to MRI (e.g., metal in the subject’s body), in either parent or offspring reported by the parents. However, it is still possible that mothers omitted reporting past or current use of steroids, including contraceptives, that may affect brain morphometry (Pietzet et al., 2010), because these are commonly taken among healthy people. The Stanford University and University of California San Francisco Panel on Human Subjects in Medical Research approved the study. After complete description of the study to the participants, written informed consent and assent were obtained from parents and children, respectively. Thirty-one families had one child and four families had two children. We created four parent–offspring subgroups, including 16 mother–daughter, 18 mother–son, 15 father–daughter, and 18 father–son pairs.

Demographic, cognitive, and behavioral assessments. Behavioral data (such as mental health status) of offspring were obtained by the Behavioral Assessment System for Children, Second Edition (BASC-2; Reynolds and Kamphaus, 2004), which is a multimethod, multidimensional system used to evaluate the adaptive and problematic behavior of children and young adults aged 2–25 years. We collected parent-rating scales (PRS) of nine clinical scales, including aggression, anxiety, attention problems, atypicality, conduct problems, depression, hyperactivity, somatization, and withdrawal, and five adaptive scales, including activities of daily living, adaptability, functional communication, leadership, and social skills. The BASC-2 was normed in the United States using a large representative sample of youth (including >13,000 cases) from across the nation. Aged-normed T scores are continuously distributed within the population, with a mean of 50 and an SD of 10. A high score implies more emotional and behavioral problems, except for the adaptive skills scale for which a high score implies more attributes that contribute to healthy functioning. More specifically, on the clinical scales, T scores from 60 to 69 indicate “at-risk” behaviors and 70 and above indicate “clinically significant” concerns. Conversely, analogous cutoffs are established for the adaptive skills scale whereby T scores from 31 to 40 are considered to be at-risk and 30 or less are considered to be clinically significant.

To evaluate potential sex differences in age in our samples, we used independent Student’s t tests for age in parents and offspring, respectively. Because the BASC-2 PRS consists of 14 subscales, we performed a multivariate analysis of covariance (MANCOVA) to compare group differences between male and female offspring using these BASC-2 PRS subscales as dependent variables. Then, if a main effect of group on the MANCOVA was confirmed, a post hoc ANCOVA was performed. Although there were no significant differences in age, age was included as

covariate in the analyses because of the relatively wide range in age of the children (age range, 5–13 years). Because all data were originally collected for the purpose of a study examining the neural bases of academic achievement in the offspring, there were no relevant behavioral data in parents (except for measures such as IQ).

**Image acquisition and preprocessing.** MR images were acquired using a 3 T whole-body GE-Signa HDxt scanner (GE Healthcare) with a quadrature head coil at the Lucas Center for Imaging at Stanford University. For voxel-based morphometry (VBM), high-resolution T1 anatomical scans were obtained using a fast spoiled gradient recalled echo pulse sequence (160 coronal slices; TR, 8.5 ms; TE, 1.7 ms; inversion time, 300 ms; flip angle, 15°; number of excitations, 1; FOV, 22 cm; matrix, 256 × 256; thickness, 1.2 mm; acquisition time, 4 min 34 s). Images were first checked visually for scanner artifacts and anatomical anomalies. Preprocessing was done using DARTEL (Ashburner, 2007) for VBM in SPM8 (http://www.fil.ion.ucl.ac.uk/spm). We further selected the modulated normalized nonlinear-only option, which results in an analysis of relative differences in regional GMV, corrected for individual brain size. This allows comparing the absolute amount of tissue corrected for individual brain sizes.

**Parent–offspring correlation in corticolimbic circuitry.** First, we performed voxelwise correlation analysis of volumes between mother and daughter, controlling for daughter’s age and limiting the analysis to the region of interest (ROI) using the BFM (Biological Parametric Mapping) toolbox (Casanova et al., 2007). We created one corticolimbic ROI, including bilateral amygdala, ACC, vmPFC including the OFC and gyrus rectus, hippocampus, and parahippocampus gyrus defined by Automated Talairach Atlas Label (Lancaster et al., 2000) in the Wake Forest University PickAtlas toolbox (http://fmri.wfubmc.edu/cms/software#PickAtlas). ROI analyses were performed using a statistical threshold of \( p = 0.05 \) for voxel height, which then was thresholded at a cluster threshold of \( p = 0.05 \) for familywise error (FWE). This resulted in a brain map showing significant positive GMV correlations between mother and daughter.

Second, because our primary goal was to examine the specificity of the parent–offspring GMV relationship, the next steps were to create brain maps that compared correlation coefficients \( r \) between different parent–offspring groups on a voxelwise basis in the corticolimbic ROI. Based on our a priori hypothesis, we generated three brain maps: (1) correlation coefficients (association) that were significantly stronger between mother–daughter compared with mother–son pairs to examine whether mothers show stronger effects on daughters than sons; (2) mother–daughter greater than father–daughter association to examine whether mothers compared with fathers show stronger effects on daughters; and (3) mother–daughter greater than father–son association to show, to the extent possible, sex-specific effects. One challenge in testing for statistical differences between correlations in our data is the partial dependency of the sample. For example, when we compare mother–daughter correlation with mother–son correlation, some observations are dependent (e.g., a mother who has a daughter and a son), but some others are not (e.g., a mother who has a daughter only). To address this statistical issue, we used a bootstrapping method (Efron and Tibshirani, 1993) to assess the significance of the difference between the two correlation coefficients. Specifically, we derived the SEs of the differences in correlations (e.g., SE of the differences in mother–daughter correlation and mother–son correlation) by repeatedly resampling the observed data. Importantly, the resampling procedure takes into account the (partial) dependency of the data, making it possible to precisely compute the SEs. Before implementing bootstrapping, each individual’s processed voxelwise GMV values within the corticolimbic ROI were extracted and converted to matrices using an in-house MATLAB-based multivariate pattern analysis toolbox (Hoeft et al., 2008, 2011). We then ran bootstrapping with an in-house R code (R Core Team, 2015). As a result, we obtained three brain maps representing significantly greater positive GMV correlation in mother–daughter pairs \( (p < 0.05) \) compared with mother–son, father–daughter, and father–son pairs, respectively. Finally, we overlapped these three brain maps and the FWE-corrected mother–daughter correlation map to identify the voxels that showed significantly greater positive correlations between mother–daughter pairs than for the other three pairings.

**Correlation between regional brain volume and behavioral data.** To examine whether the degree of GMV in brain regions that show significant positive association between mothers and daughters is associated with emotional and behavioral functioning in daughters, Pearson’s correlation analyses were performed between GMV data and standardized scores from all BASC-2 scales obtained from the daughters. Based on previous behavioral reports showing female–specific transmission patterns in depression (Davies and Windle, 1997; Goodman and Gotlib, 1999; Goodman, 2007; Thompson et al., 2014), we hypothesized that there may be associations between daughters’ GMV and their BASC-2 depression subscales. GMV data were extracted from clusters in the amygdala, ACC, OFC, gyrus rectus, and hippocampus that showed significant positive associations between mothers and daughters compared with other parent–offspring dyads within the corticolimbic ROI. All behavioral data were originally collected for the purpose of a different study, and hence we only had data from 10 of 16 daughters, making these results tentative and exploratory at best.

**Results**

**Corticolimbic ROI analysis**

In offspring, a MANCOVA showed no significant sex differences for \( T \) scores in the BASC-2 PRS scales \( (\text{Wilks’ Lambda} = 0.08, \)
Table 1

Figure 1. GMV associations between parents and offspring. Top, Brain regions showing significantly greater positive correlations in mother–daughter pairs compared with mother–son pairs. Middle, Brain regions showing significantly greater positive correlations in mother–daughter pairs compared with father–daughter pairs. Bottom, Brain regions showing significantly greater positive correlations in mother–son pairs compared with father–son pairs. All comparisons showed similar morphometric association patterns. Axial view of Talairach coordinates: z, −27, −22, −17, −12, −7, −2. Sagittal view of Talairach coordinates: x, 29, 13, −3. Lt, Left; Rt, right. For all analyses, the statistical threshold is set at $p = 0.05$ corrected.

Correlation between regional brain volume and behavioral data in daughters

There was a positive correlation between GMV of the gyrus rectus and adaptability $T$ scores ($r = 0.710$, $p = 0.021$ uncorrected); however, these results did not reach statistical significance when applying Bonferroni’s correction. There was no significant correlation between GMV of the other brain regions and any behavioral measures despite other subscales showing similar or even greater variance (all $p$ values >0.1 corrected).

Discussion

The present study found female-specific intergenerational effects on brain structure between biological parent–offspring dyads. Specifically, consistent with our hypothesis, positive associations of regional GMV between mothers and daughters were significantly greater than mother–son, father–daughter, and father–son associations in the amygdala, hippocampus, ACC, and vmPFC, which included the gyrus rectus and OFC. These findings may indicate that the daughter’s corticolimbic circuitry is associated specifically with that of the mother’s. A growing number of animal and human neuroimaging studies have implicated corticolimbic circuitry, specifically the amygdala, ACC, and vmPFC, as the biological substrates of emotion regulation. The amygdala regulates a variety of emotions, including depression, anxiety, and fear, and plays a major role in emotional memory processing and reactivity of the HPA axis to stress (Banks et al., 2007). The ventral ACC, in particular the pregenual and subgenual ACC, has functional connections with OFC, amygdala, and hippocampus and participates generally in emotion regulation (Drevets et al., 2008; Pizzagalli, 2011). The vmPFC, via its direct structural and functional connections with the amygdala (Ghashghaei et al., 2007), modulates emotional responses through GABAergic inhibitory projections (Akirav et al., 2006). Dysfunction in this circuitry is associated strongly with conditions such as mood and anxiety disorders (Price and Drevets, 2010). In addition, the finding in the hippocampus further supports our hypothesis. The hippocampus is one of the key components of emotional regulatory networks in the brain. Previous

studies have reported that depression is associated with smaller hippocampal volume because of glucocorticoid neurotoxicity and stress-induced reduction in neurotrophic factors and neurogenesis (Sheline, 2011).

In this study, we show the intriguing finding that mother’s and daughter’s corticolimbic morphology was more similar than other parent–offspring pairs. Our study provides novel neurobiological support for female-specific transmission patterns in depression. Several previous studies have revealed that healthy controls with a family history of depression (high-risk group) compared with those with no family history of any psychiatric disease (low-risk group) had structural abnormalities in corticolimbic circuitry, including smaller hippocampus, smaller ACC, and larger amygdala volumes. They suggested that these structural anomalies may be potential neurobiological markers of vulnerability for depression (Boes et al., 2008; Chen et al., 2010; Romanzuk-Seiferth et al., 2014). Moreover, other data suggest that the combination of early-life adversity and smaller hippocampal size significantly increases the vulnerability for depression (Rao et al., 2010). Together, our findings indicate that, if mothers have brain structural anomalies in the corticolimbic circuitry, their female but not male offspring are more likely to have similar abnormal structural patterns in the same brain regions. Although additional research is warranted, these matrilineal associations may be tightly linked to greater vulnerability for daughters but not sons in developing depression when their mothers have depression.

It is currently difficult to point to the precise underlying mechanisms of our findings because of lack of previous studies. Nonetheless, one may speculate that genetic, prenatal, and postnatal environmental factors and their interactions may underlie female-specific intergenerational patterns in depression symptoms, brain morphometry, and gene expression patterns in the corticolimbic circuitry. In addition to animal studies mentioned in the Introduction, gestational stress leads to increased corticotropin releasing hormone mRNA in the amygdala (Cratty et al., 1995), and the amount of maternal care influences epigenetic modification (methylation) to hypothalamic estrogen receptor α in female rats (Champagne et al., 2006). These studies provide the underlying neurobiological evidence of female-specific intergenerational effects by examining gene expression in brain tissue. Furthermore, female but not male offspring of mice show a reduction in hippocampal glial count in the pyramidal layer after prenatal stress (Behan et al., 2011). In humans, one multisite survey in both genetically related and unrelated parent–offspring pairs reported that girls may be more prone to the negative influences of maternal depression symptoms than boys through environmental processes (Lewis et al., 2011). A previous study revealed that higher maternal prenatal cortisol level and offspring’s depression problems were associated with larger right amygdala volumes in girls but not boys (Buss et al., 2012). These findings indicate the presence of female-specific placental adaptation to stress exposure (Clifton, 2010), which may influence more similar neurodevelopmental trajectory among females compared with males in the corticolimbic circuitry. Longitudinal studies in families with different genetic, prenatal, and postnatal environmental influences are needed to examine the relationship between maternal stress, endocrine effects, and brain development in mothers and their daughters.

Furthermore, in the gyrus rectus, which is the medial part of the OFC, a positive correlation between GMV of mothers and their adaptability in the BASC-2 was found, such that larger volumes of the OFC may be related to higher levels of adaptability. This finding may support previous animal studies indicating that the OFC contributes to emotional and social adaptive behavior (Roberts, 2006). Behavioral measures in the current study were collected for the broader purpose of another study and were not optimized to examine intergenerational effects; hence, together with the small sample and lack of measures in parents, the results of this exploratory analysis should be interpreted with caution.

There has been increasing consensus on sex differences in gray matter developmental trajectories (Giedd et al., 1999; Bellis et al., 2001). Cerebral volume and GMV in the frontal and parietal lobes peak earlier in girls than in boys (Lenroot and Giedd, 2006). Moreover, sex differences have been demonstrated in the hippocampus (larger in females), amygdala (larger in males), and thalamus (larger in males; Koolscijn and Crone, 2013); however, our study found that mother–daughter pairs consistently demonstrated significantly greater positive GMV correlations compared with the other parent–offspring pairs not only in the amygdala and medial PFC in which volume is larger in males than in females but also in the OFC and hippocampus in which volume is larger in females than in males (Cosgrove et al., 2007; Koolscijn and Crone, 2013). These results indicate that sex differences in these brain volumes cannot account for the pattern of associations we observed. Additional research is needed to examine the mechanisms underlying the consistent female-specific association patterns in each brain region showing a pronounced sexual dimorphism in development within the corticolimbic circuitry.

Several limitations of this study should be noted. First, because we only used genetically related families, in which genetic, prenatal, and postnatal environments are shared and did not include in vitro fertilization (IVF) and adoptive families, we were
unable to dissociate the influence of these three factors on our neurobiological findings of intergenerational effects. Second, we did not directly examine how functional and anatomical connectivities within corticolimbic circuitry are mediated by the intergenerational effects in this sample. Therefore, additional studies using multimodal imaging in three different groups (genetic, IVF, and adoptive groups) are needed. Third, we only focused on matrilineal transmission patterns in the human brain based on our hypothesis; however, Rodgers et al. (2013, 2015) found that stressed male mice show an increase in micro-RNAs in their sperm, leading to reduced HPA stress axis responsivity in adult offspring. The result indicates novel epigenetic mechanisms of paternal transmission patterns in neuropsychiatric disorders including depression. Thus, it is also important to examine paternal intergenerational transmission effects in the corticolimbic circuitry in future studies. Fourth, the human amygdala appears to undergo rapid development early in life (Hare et al., 2008). Conversely, in rodent models, the vmPFC develops later in life (Van Eden and Uylings, 1985) and connectivity between the amygdala and the vmPFC does not emerge until adolescence (Cunningham et al., 2002). Therefore, longitudinal studies are required to explore how our findings of female-specific intergenerational patterns are affected by the developmental trajectory in the corticolimbic circuitry. In the current study, although cross-sectional, we attempted to capture children with minimal influence of puberty and extra-family environment on the brain (Dahl, 2004). Finally, because of the relatively small sample size and exploratory nature of our analysis, the current findings are preliminary and require additional research with a larger sample. However, the current study represents the first study to examine parental transmission patterns of corticolimbic morphometry in humans in vivo.

In summary, to our knowledge, this is the first study to investigate intergenerational transmission patterns in the human brain using neuroimaging. We demonstrate a significant matrilineal association between parents and their offspring in a brain circuit associated with emotion regulation as measured by regional GMV. Our results provide new insights into the potential neuroanatomical basis of female-specific intergenerational effects of psychiatric conditions, especially in depression. Findings from our study have the potential to bridge animal work and clinical observations. Ultimately, findings such as ours may have important implications for furthering the understanding and the creation of developmental stage-specific and circuit-based treatment intervention of mental illnesses, such as depression, that show intergenerational effects.
