Abstract

Purpose: There is a growing interest in using circulating tumor DNA (ctDNA) testing in patients with cancer.

Experimental Design: A total of 168 patients with diverse cancers were analyzed. Patients had digital next-generation sequencing (54 cancer-related gene panel including amplifications in ERBB2, EGFR, and MET) performed on their plasma. Type of genomic alterations, potential actionability, concordance with tissue testing, and patient outcome were examined.

Results: Fifty-eight percent of patients (98/168) had ≥1 ctDNA alteration(s). Of the 98 patients with alterations, 71.4% had ≥1 alteration potentially actionable by an FDA-approved drug. The median time interval between the tissue biopsy and the blood draw was 2.7 months for patients with ≥1 alteration in common compared with 14.4 months (P = 0.006) for the patients in whom no common alterations were identified in the tissue and plasma. Overall concordance rates for tissue and ctDNA were 70.3% for TP53 and EGFR, 88.1% for PIK3CA, and 93.1% for ERBB2 alterations. There was a significant correlation between the cases with ≥1 alteration with ctDNA ≥ 5% and shorter survival (median = 4.03 months vs. not reached at median follow-up of 6.1 months; P < 0.001). Finally, 5 of the 12 evaluable patients (42%) matched to a treatment targeting an alteration(s) detected in their ctDNA test achieved stable disease ≥ 6 months/partial remission compared with 2 of 28 patients (7.1%) for the unmatched patients, P = 0.02.

Conclusions: Our initial study demonstrates that ctDNA tests provide information complementary to that in tissue biopsies and may be useful in determining prognosis and treatment.

Introduction

Performing tumor biopsies remains the standard practice to establish cancer diagnosis and to detect potentially actionable alterations (1, 2). However, tissue biopsies have limitations as they are invasive, expensive, and can expose the patient to pain and complications. Multiple serial biopsies are also unpalatable to patients, and some tumor sites are difficult to access. In addition, a biopsy of the primary site or one metastatic site may not reflect the complete genomic makeup of the malignancy, as heterogeneity can be found both between tumor lesions and within the same tumor (3–5).

Circulating tumor DNA (ctDNA) is composed of small fragments (about 150–200 base pairs) of DNA that are released from cells undergoing apoptosis or necrosis in malignant lesions (primary or metastatic) and can be detected and sequenced in the blood of patients with cancer (6, 7). Detection of cell-free DNA was first described in 1987 by Stroun and colleagues (8), and numerous articles were published in the past few years, indicative of a growing interest in this noninvasive diagnostic method (9–18). Potential application scenarios include using ctDNA to supplement or substitute for tissue biopsies, especially in cases where tissue biopsies are risky or the quantity/quality of the tissue biopsied does not allow testing, and to use repeat sampling and genomic profiling to detect tumor evolution, response, and resistance (6, 19–21). Of interest, fluids such as urine can also be used to detect ctDNA (22, 23). Finally, the use of ctDNA tests would increase chances to interrogate shed DNA from multiple metastases, perhaps better reflecting heterogeneity of the cancer burden in its entirety.

Herein, we report our clinical experience with the use of ctDNA testing in 168 patients with diverse cancers followed at UC San Diego Moores Cancer Center, La Jolla, CA.

Materials and Methods

Patients

We retrospectively reviewed the clinicopathologic and outcome data of 168 consecutive patients with diverse solid cancers followed at UC San Diego Moores Cancer Center, for whom molecular testing (ctDNA test) had been performed on their plasma (June 2014 until February 2015). This study [PREDICT-UCSD (Profile Related Evidence Determining Individualized Cancer Therapy); NCT02478931] was performed and consents...
Translational Relevance

We are currently facing many changes in traditional paradigms for cancer treatment. One of the most striking advances is a deeper understanding of genomic abnormalities that drive a variety of tumors, offering unique opportunities of new treatment options. Analysis of cell-free DNA in the plasma of patients with cancer using next-generation sequencing is a potentially powerful tool for the detection/monitoring of alterations present in circulating tumor DNA (ctDNA). Our results demonstrate that of the 98 patients with alterations, 71.4% had ≥ 1 alteration potentially actionable by an FDA-approved drug. Furthermore, ctDNA tests provide information complementary to that in tissue biopsies. In addition, ctDNA tests may be useful in determining prognosis (percentages of ctDNA ≥ 5% correlated with shorter survival) and treatment, as patients who were matched to drugs targeting alterations identified in their plasma achieved encouraging rates of stable disease ≥ 6 months/partial remission (42%).

Sequencing

Digital Sequencing was performed by Guardant Health, Inc. (Guardant360, www.guardanthealth.com/guardant360/), a Clinical Laboratory Improvement Amendments (CLIA)-certified and College of American Pathologists (CAP)-accredited clinical laboratory. This test identifies potential tumor-related genomic point mutations within 54 cancer-related genes (Supplementary Table S1) as well as amplifications in ERBB2, EGFR, and MET through analysis of cell-free DNA extracted from plasma (from two 10-mL blood tubes). This ctDNA assay has high sensitivity (detects 85%-95% of the single-nucleotide variants detected in tissue in advanced cancer patients) and analytic specificity (> 99.9999%; ref. 24).

In addition, N = 101/168 patients (60%) who had ctDNA results also had next-generation sequencing (NGS) performed on their tissue. For these 101 patients, tissue testing was done by Foundation Medicine (FoundationOne, http://www.foundationone.com). Hybridization-based capture from 315 cancer-related genes plus introns from 28 genes often rearranged or altered in cancer (N = 63 patients) and from 236 cancer-related genes and 47 introns of 19 genes commonly rearranged in cancer (N = 38 patients) was performed. In a study using 249 formalin-fixed paraffin-embedded cancer specimens characterized by established assays, the FoundationOne test sensitivity achieved was 95% to 99% across alteration types, with high specificity (positive predictive value >99%; ref. 25).

Concordance rate

For the N = 101 who had both types of tests (plasma and tissue), we aimed to assess the concordance. As the tissue and plasma tests sequenced different gene panels, we only considered alterations in common for both tests [i.e., alterations tested and which could be detected by both tests (N = 54 genes)]. Of the 101 patients, 63 patients had ≥ 1 alteration(s) detected in the tissue which could have been detected by the ctDNA test. We looked at specific concordance rates for TP53, EGFR, PIK3CA, and ERBB2 and computed the corresponding kappa (k) statistics, which is a conservative measurement of relative agreement that takes into account agreement by chance. Kappa ranges from k = 1 (perfect agreement) to k = 0 (no agreement other than would be expected by chance).

Therapy and actionability

Treatment was considered matched if at least one agent in the treatment regimen targeted at least one aberration or pathway component aberrant in a patient’s molecular profile or a functionally active protein preferentially expressed in the tumor (as assessed by any standard-of-care testing, e.g., estrogen receptor or HER2 as well as NGS performed on tissue and/or ctDNA).

Statistical analysis

When appropriate, median and 95% confidence intervals (CI) or range were reported. The following clinical endpoints were considered: (i) rate of [stable disease (SD) ≥ 6 months/ partial response (PR)/complete response (CR)]; (ii) progression-free survival (PFS) of the first line of therapy given after ctDNA results (PFS2); and (iii) overall survival (OS). SD, PR, and CR were determined per assessment of the treating physician. PFS was defined as the time from the beginning of therapy to progression or the time to the last follow-up for patients that were progression-free (patients that were progression-free on the date of last follow-up were censored on that date). OS was defined as the time from the ctDNA test results date to death or last follow-up date for patients who were alive (the latter were censored on that date). The cut-off date of the analysis was June 30, 2015; all patients who were progression-free (for PFS) or alive (for OS) as of the date of analysis were censored on that date unless their date of last follow-up was earlier, in which case that was the date of censoring.

Whenever appropriate, χ² tests were used to compare categorical variables and the nonparametric Mann–Whitney U test to compare two groups on one continuous variable. Binary logistic regressions were performed for categorical endpoints and multiple linear regressions for continuous variables. PFS and OS were analyzed by the Kaplan–Meier method (26) and the log-rank test was used to compare variables. Statistical analysis was performed by MS with IBM Statistics SPSS version 22.0.

Results

Patients’ characteristics

One hundred and sixty eight consecutive patients who were seen at UCSD Moores Cancer Center and had ctDNA molecular testing performed were reviewed and analyzed. There was a slight preponderance of women over men (58%). The median age at diagnosis was 54.5 years (95% CI, 51–59 years). The majority of our patient population was Caucasian (67%), followed by Asian (15.5%), and other (8.9%). The most common primary tumor sites were brain (33.3%), followed by lung (28%), and breast (21.4%). The majority of patients (85.1%) had metastatic/recurrent/advanced unresectable disease at the time of ctDNA testing (Table 1 and Supplementary Table S2). Many patients that were tested and did not have metastatic/recurrent/advanced unresectable disease had brain tumors [which comprised 56 of our 168 patients tested (18 of whom did not have metastatic/recurrent disease at the time of testing)].

Description of alterations and actionability of the detected alterations

Excluding synonymous alterations, patients had a median of one alteration (range, 0–19). Fifty-eight percent of patients (98/168) had ≥1 alteration(s) identified in their plasma. The most common alterations were in TP53 (31.5%), followed by EGFR (17.3%), and MET (10.1%; Fig. 1A). In total, 244 alterations (215 mutations and 29 amplifications) were identified in 168 patients. Of the 98 patients with alterations, N = 77 (78.6%) had mutations only, N = 17 (17.3%) had both mutation(s) and amplification(s), and N = 4 (4.1%) had only amplification(s).

We then examined whether we could identify variables correlating with the number of alterations. In a univariable analysis, patients with gastrointestinal cancers, as well as with lymph node, bone, lung, and liver metastasis had a significantly higher number of alterations, whereas patients with brain tumors had significantly less detectable alterations. Even so, 16 of 56 patients (28.6%) with brain tumors had an alteration, with a median number of alterations in all brain tumor patients of 0 (range, 0–2). In the multivariable analysis, only gastrointestinal cancers (P = 0.001) was an independent predictor of a higher number of alterations, whereas brain tumors correlated with fewer alterations (P = 0.019) detected in the plasma (Table 2).

Of the 98 patients with alterations, 74 (75.5%) had at least one alteration that could potentially be targeted by an experimental drug or an FDA-approved drug (Fig. 1B). Of interest, 71.4% of patients with alterations had ≥1 alteration potentially actionable by an FDA-approved drug. However, a limited percentage of patients (12%) had alterations potentially actionable by a drug approved by the FDA for their disease (on-label use).

Concordance of the ctDNA test with tissue genomic testing

Of the 168 patients who had ctDNA test results, 101 (60%) also had tissue genomic testing (FoundationOne, see Materials and Methods). However, only 63 patients had alterations in the tissue that also were part of the ctDNA panel used. Twenty-two of the 63 patients (35%) had ≥1 alteration in common between the tissue and ctDNA. In these 22 patients, the median time interval between the tissue biopsy and the blood draw was 2.7 months compared with 14.4 months (P = 0.006) in the 41 of 63 (65%) patients in whom no common alterations were identified in the tissue and plasma (Fig. 2A).

Finally, in addition to comparing the molecular profiles in their entirety, we studied concordance for the most frequent alterations (Table 3; Fig. 2B). We found that the overall concordance rates (both tests positive/both tests negative in the 101 patients who had both tissue and ctDNA testings) were 70.3% for TP53 and EGFR alterations, 88.1% for PIK3CA, and 93.1% for ERBB2.

We also compared the concordance rates between tissue and ctDNA profiling in patients for whom the time interval between the tissue biopsy and blood draw used for testing was ≤6 months (N = 39 patients) versus those in whom the time interval was >6 months (N = 62) and found that the concordance rate for TP53 alterations was 82.1% versus 63% (P = 0.046); for EGFR alterations, the concordance rate of ≤6 months versus >6 months was 69% versus 71%; for PIK3CA, 85% versus 90%; and for ERBB2, 97% versus 87% (not significant P values; Table 3, Fig. 2B). Of note, we observed that MET alterations were only detected in ctDNA tests in the 101 patients who had both ctDNA and tissue testings (9/101 = 9% in ctDNA vs. 0% in tissue).

Analysis of patient outcome

Patients had a median of one prior line of therapy (range, 0–11) before ctDNA testing. Of the 168 patients, 33 (19.6%) were treated with a ‘matched’ therapy following molecular profile results, and 39 (23.2%) with an ‘unmatched’ therapy; the remaining patients were not evaluable for treatment after test results, mainly because they died before treatment, were only treated with surgery and adjuvant therapy, were still on prior therapy, or were lost to follow-up before treatment (Supplementary Fig S1).

The median time from tests results until treatment initiation was 2 months (95% CI, 1.4–2.7 months), often because physicians ordered testing before patients had failed their prior therapy to have a plan available in case of failure (2). The median follow-up time from ctDNA results was 6.1 months (95% CI, 5.6–6.5). The median therapy line in the advanced/metastatic setting was 2 (95% CI, 1–3; range 1–8) for the unmatched patients, versus 2 (95% CI, 2–3; range 1–10) for the matched patients (P = 0.238).

Of the 33 patients who received a matched therapy, the drug was targeting an alteration(s) detected by the ctDNA test for 15 patients (45.5%). Of the 12 patients evaluable for response (3 patients, too early to assess), 5 (42%) achieved SD ≥6 months/PR (Supplementary Table S3). In 3 of the 5 responders, the relevant actionable alteration was found first in ctDNA and later confirmed by tissue NGS. Of the 39 unmatched patients, 28 were evaluable for response. Of these 28 patients, 2 (7.1%) achieved SD ≥6 months/PR (P = 0.02 comparing 5/12 vs. 2/28). For these 40 evaluable patients, the median line of therapy for the 12 matched patients was 2.5 (95% CI, 2–4) versus 2 (95% CI, 1–3) for the 28 unmatched patients (P = 0.291). Matched patients had their
A  Frequent alterations: overall and per tumor type

B  Potential actionability overview of the alterations identified

Figure 1.
Frequent alterations identified and potential actionability. A, bar graph representing the most frequent alterations identified in the overall population (N = 168) and per the tumor types with at least 10 patients: brain (N = 56), lung (N = 47), breast (N = 36), and gastrointestinal (N = 13, of whom three had colorectal cancer). Patients with brain tumors had significantly less alterations identified (P < 0.001). In non-brain cancers (N = 112), we identified alterations in 82 of 112 (73%) patients. Only the five most frequent genes are represented (for brain and gastrointestinal cancers, we only represented the genes altered in ≥ 1 patients and for lung cancers ALK and NOTCH1 had the same frequency). Use of Liquid Biopsies in Clinical Oncology

cTissue results after a median of 30.7 months after diagnosis versus 16.0 months for the unmatched patients, though this difference was not statistically significant ($P = 0.637$).

**Percentage of ctDNA detected**

The median percentage of ctDNA detected for each mutation was 0.45% (range, 0.1–75%; 95% CI, 0.3–0.6). We investigated whether or not the percentage of ctDNA correlated with clinical outcome parameters. We observed a strong correlation between the cases with at least one gene altered with a percentage of ctDNA ≥5% and shorter OS (median OS = 4.03 months vs. not reached at a median follow-up of 6.1 months; $P = 0.0001$ in multivariable analysis; Fig. 3). Patients with at least one alteration with ctDNA ≥5% had a statistically higher median number of prior lines of therapy before ctDNA testing compared with patients with ctDNA <5% [2 (95% CI, 1–3) vs. 1 (95% CI, 0–1); $P = 0.009$]. However, multivariate analysis of prognosis revealed that ctDNA only was significant for OS.

Regardless of treatment, patients with at least one alteration with ≥5% ctDNA also had a shorter PFS [2.1 months (95% CI, 1.2–3.0) vs. 4.0 months (95% CI, 2.5–5.5)] for the next immediate therapy following ctDNA testing, that did not reach statistical significance ($P = 0.124$). No difference was noted for the rate of SD ≥6 months/PR/CR (18.2% vs. 17.5%, $P = 1.0$). Finally, we observed that patients with ≥5% ctDNA for at least one alteration also had a higher median number of alterations [3 (95% CI, 2–4] vs. 1 (95% CI, 1–1); $P = 0.0001$].

**Discussion**

This study describes our initial experience with using ctDNA molecular diagnostic tests, including the types of alterations detected and their actionability, the concordance with tissue testing, and the outcomes of patients treated with a matched therapy. Overall, 98 of our patients (58%) showed at least one alteration in their ctDNA. In tumors other than those of the brain, the percentage was 73%, whereas in brain tumors, it was 29%. In a multivariable analysis, only gastrointestinal cancers ($P = 0.001$) were independent predictors of a higher number of alterations detected in the plasma (Table 2). It is conceivable that the high vascularization of these type of tumors might have increased the accessibility and detection rate of alterations (27–29). In contrast, patients with brain tumors had significantly fewer alterations (even though about 29% of patients with brain tumors had detectable alterations). Bettegowda and colleagues (30) demonstrated that ctDNA was detectable in >75% of patients with various cancers, and in less than 50% of primary brain cancers ($N = 640$ patients). Therefore, based on the study above and our current study, the blood–brain barrier does not preclude primary brain tumors from shedding ctDNA into the circulation (31). For patients with primary brain cancers, cerebrospinal fluid may also serve as an alternative "liquid biopsy" (32).

In our study, when examining the concordance in patients who had both a tissue and ctDNA testing, 22 of 63 (35%) of patients had ≥1 alteration in common (Fig. 2A). These 22 patients had a median time interval between the tissue biopsy and blood draw (used for the ctDNA test) of 2.7 months compared with 14.4 for patients in whom no common alterations were found ($P = 0.006$), consistent with the concept that the genomic background of tumors changes over time (33, 34). When examining the percentage agreement for specific alterations (TP53, EGFR, PIK3CA, and ERBB2), the concordance rates between ctDNA and tissue NGS were in the same range (70%–93%) of those reported previously (about 67%–99%; refs. 11, 17, 33, 36). Although the number of patients was low, we observed that MET alterations were only detected in ctDNA (not in tissue in the 101 patients who had both tested), consistent with prior results showing higher rates of MET alterations in ctDNA (37); this conceivably could be due to the propensity of DNA-bearing MET-related alterations to

Figure 2.
Alteration detection by tissue and ctDNA tests. A, diagram showing the percentage of common alterations between the tissue and ctDNA tests. B, Venn diagrams representing the proportion of patients for whom the alteration was only detected in the tissue, detected in both the tissue and ctDNA (positive concordance), and in whom the alteration was only detected in ctDNA. See also Table 3 for additional information.
be shed into the blood. Recently, Rothé and colleagues (38) investigated whether or not plasma could be used as an alternative to biopsies from metastatic sites for detection of molecular alterations. They analyzed and compared 69 tumor samples and 31 plasma samples originating from 17 patients with metastatic breast cancer and found that, in 13 of 17 (76%) patients, tumor and plasma provided concordant results when tumor and plasma were collected at the same time point. In comparison, we had 39 patients who had tumor and blood collected at a close time point (<6 months apart), and there was between 69% and 87% concordance for specific alterations (Table 3).

Of interest, a focused analysis on the positive cases (Fig. 2B) revealed that both tests could independently detect alterations not found in the other test, stressing the clinical value and complementary nature of the techniques. This observation is perhaps not surprising considering the distinct advantages and disadvantages of each technique. For instance, ctDNA tests can theoretically detect shed DNA from multiple metastatic sites, whereas tissue biopsy DNA tests would discern only alterations in the small piece of tissue evaluated. On the other hand, ctDNA tests may not be sensitive enough to detect alterations that are important and easily identified in a tissue test, and not all sites of disease may shed DNA into the circulation. From a logistical standpoint, the median turnover time (from blood sample collection until results) for the ctDNA test was 14 days. In comparison, our previous report demonstrated that the median time from tissue assay order until results is about a month (including ~15 days necessary for pathologic specimen retrieval; ref. 2). In addition, a blood draw is less invasive and less costly than a tissue biopsy, thus allowing for repeat testing. In an exploratory analysis, more patients achieved a SD ≥6 months/PR/CR in the matched group according to ctDNA results compared with the unmatched patients, [5/12 patients (42%) vs. 2/28 patients (7.1%); P = 0.02]. The main

OS according to the percentage of ctDNA. N = 154/168 patients evaluable for OS analysis (N = 14 patients died or were lost to follow-up before ctDNA results). Median OS for patients with ctDNA > 5% is 4.03 months versus not reached for patients with ctDNA < 5% (P = 0.0001 in multivariable analysis, median follow-up time = 6.1 months).

Note. Concordance was determined when both the tissue and the ctDNA were negative or positive. Concordance among positive concordant alterations was detected in both tests. Concordance among negative concordant alterations was determined when both the tissue and the ctDNA were negative. Concordance among negative discordant alterations was determined when both the tissue and the ctDNA were positive. Concordance among negative discordant alterations was determined when both the tissue and the ctDNA were negative. Concordance among positive discordant alterations was determined when both the tissue and the ctDNA were positive. Concordance among positive discordant alterations was determined when both the tissue and the ctDNA were negative. Concordance among positive discordant alterations was determined when both the tissue and the ctDNA were positive. Concordance among positive discordant alterations was determined when both the tissue and the ctDNA were negative.
reasons that patients were treated with an unmatched therapy were that they did not have any detectable alterations, no alterations were targetable, matching drug(s) were unavailable (e.g., clinical trial(s) too far away, no insurance coverage), and patient or physician choice (2, 39). Although it was not statistically significant, we observed that the median line of therapy for the evaluable matched patients was higher, as well as the time from diagnosis to molecular results, possibly suggesting that oncologists resort to treating patients with a matched therapy later in the disease course.

When we compared patients with a percentage of ctDNA ≥ 5% versus < 5%, we found that patients with at least one altered gene detected at levels ≥ 5% in the plasma had a significantly shorter survival (median survival = 4.03 months vs. not reached; P < 0.0001; Fig. 3) and PFS (for the first therapy after ctDNA test; 2.1 months vs. 4.0 months; P = 0.124), consistent with prior studies describing prognostic value of ctDNA (6, 30, 40, 41).

Our observations have several limitations. First, our study was retrospective. Hence, there could be unknown biases that influenced our analysis, despite the inclusion of multivariate analysis. Furthermore, when examining matched versus unmatched patients, the numbers of patients were small. Prospective studies are needed to further define the value of ctDNA tests for treatment. In addition, some of our patients did not have concurrent tissue and ctDNA biopsies and only the genes in common to both tissue and ctDNA testing panels were included, making comparison of these modalities a challenge. On the other hand, the range of intervals between tissue and ctDNA tests allowed us to examine the influence of temporal separation of tissue biopsy and ctDNA test on molecular results and to observe that the longer the time interval between these tests, the more disparate the results. Finally, our patient population was heterogeneous, which could imply that the results may be generalizable across cancers, but it limited our understanding of individual tumor types.

To conclude, 58% of our patients had a molecular alteration and in 71% of the patients with alterations (42% of the total patients), there was an alteration that was potentially pharmacologically tractable by an FDA-approved drug (albeit often off-label; Fig. 1B). Unexpectedly, 28.6% (16/56) patients with alterations were targetable, matching drug(s) were unavailable (e.g., clinical trial(s) too far away, no insurance coverage), and patient or physician choice. In addition, some of our patients did not have concurrent tissue and ctDNA biopsies and only the genes in common to both tissue and ctDNA testing panels were included, making comparison of these modalities a challenge.

Disclosure of Potential Conflicts of Interest
S.P. Patel reports receiving speakers bureau honoraria from Boehringer Ingelheim and Merck, is a consultant/advisory board member for Eli Lilly and Pfizer, and reports receiving commercial research support from Guardant Health. B.A. Parker has ownership interest (including patents) in Merck, and reports receiving commercial research grants from Genentech and ClaxsonUthkline. R. Kurzrock is an employee of and has ownership interest (including patents) in Curematch, Inc. and Novena, Inc., is a consultant/advisory board member for Actuate Therapeutics and Sequenom, and reports receiving commercial research grants from Foundation Medicine, Genentech, Guardant, Merck Serono, Pfizer, and Sequenom. No potential conflicts of interest were disclosed by the other authors.

Authors' Contributions

Conception and design: M. Schwaederle, S. Kesari, R. Kurzrock
Development of methodology: M. Schwaederle
Acquisition of data (provided animals, acquired and managed patients, provided facilities, etc.): M. Schwaederle, H. Husain, P.T. Fanta, D.E. Piccioni, S. Kesari, R.B. Schwab, S.P. Patel, B.A. Parker
Analysis and interpretation of data (e.g., statistical analysis, biostatistics, computational analysis): M. Schwaederle, P.T. Fanta, D.E. Piccioni, O. Harismendy, R. Kurzrock
Writing, review, and/or revision of the manuscript: M. Schwaederle, H. Husain, P.T. Fanta, D.E. Piccioni, S. Kesari, S.P. Patel, B.A. Parker, R. Kurzrock
Administrative, technical, or material support (i.e., reporting or organizing data, constructing databases): M. Schwaederle, S. Kesari, M. Ibeda
