This work was supported by the Assistant Secretary for Fossil Energy, Office of Coal Utilization Systems, U.S. Department of Energy under Contract No. DE-AC03-76SF00098 through the Pittsburgh Energy Technology Center, Pittsburgh, PA
Abstract

The reaction of dissolved ozone with iodide, nitrite, and sulfite ions was studied using stopped-flow and pulsed-accelerated-flow techniques. The rate expressions and rate constants at 25°C are:

\[-\frac{d[O_3]}{dt} = k_7 [O_3] [I^-]\]
\[4 \times 10^9 \text{ M}^{-1} \text{ sec}^{-1} < k_7 < 7 \times 10^9 \text{ M}^{-1} \text{ sec}^{-1} \quad \text{pH 4.5 - 5} \quad \mu = 1 \times 10^{-3} \text{ M} \]

\[-\frac{d[O_3]}{dt} = k_{11} [O_3] [NO_2^-]\]
\[k_{11} = 3.0 \pm 0.2 \times 10^5 \text{ M}^{-1} \text{ sec}^{-1} \quad \text{pH 6.0 - 9.9} \quad 7 \times 10^{-3} < \mu < 2.9 \times 10^{-2} \text{ M} \]

\[-\frac{d[O_3]}{dt} = k_{17} [O_3] [SO_3^{2-}]\]
\[k_{17} = 7.5 \pm 1.8 \times 10^8 \text{ M}^{-1} \text{ sec}^{-1} \quad \text{pH 4.1 to 9.3} \quad 2 \times 10^{-3} < \mu < 4.5 \times 10^{-1} \text{ M} \]

The ozone-sulfite reaction appears to proceed primarily by a direct reaction to form sulfate. This may not be the case under very acidic and very basic conditions where free radical intermediates could influence the reaction. The ozone-iodide reaction occurs very quickly and forms I₂ as a product, presumably via an IO⁻ intermediate. No enhancement of the ozone-nitrite reaction, due to radical production by the hydroxide-ozone reaction, was observed at high pH (9.9) conditions. Ozone reactions, with rate constants (k) varying over eleven orders of magnitude, show a linear dependence on the nucleophilicity (n) of the reacting anions. The slope of log k versus n was found to be approximately 6.2.

Introduction

The reaction of aqueous ozone with a number of inorganic anions is quite rapid. The ozone-iodide reaction has not been measured because it is too fast for conventional kinetic techniques. The only estimate of the ozone-iodide reaction was obtained from observations of ozone loss from the gas phase when exposed to seawater and iodide solutions.¹ A determination of the rate constant for the ozone-iodide reaction in a more direct manner is desirable. Also, the ozone-nitrite reaction has only been studied at pH ≤ 5.¹ It was decided to extend the range of study to alkaline conditions to ensure that free radical processes at high pH conditions did not influence the rate. A number of kinetic studies have been done on the ozone-S(IV) system. Results from low pH studies (pH 2-4) had been extrapolated to higher pH conditions in order to obtain an estimate of the rate constant at conditions where SO₃²⁻ predominates, since the rate has been found to be too rapid to measure directly until recently. Since the studies to date have been done only under acidic conditions, the reaction behavior under alkaline conditions has not been definitely established.

Penkett and co-workers¹-³ have reported the kinetics of the ozone-hydrogen sulfite reaction in several studies, along with reactions of ozone with other anions. A stopped-flow system was used to study the reactions. The rate of the ozone-S(IV) reaction was found to increase with pH and fractional hydrogen ion dependence was observed. The possibility that
ozone reacted with sulfite and hydrogen sulfite ions with differing rates was not discussed. In addition to the ozone-S(IV) reaction, reactions of nitrite, ammonia, and bromide with ozone were studied with a stopped flow system. The rate constants are listed in Table I. The ozone-iodide reaction was too fast to be measured by the stopped-flow method.

Another ozone-S(IV) reaction study was done by Larson et al.\(^4\) by bubbling an ozone-oxygen mixture through a S(IV) solution and measuring the concentration of S(IV) with time. Solution pH values of 4.0 to 6.2 were used. They concluded that the values of the ozone-S(IV) rate that they observed were in reasonable agreement with the results obtained by Penkett.\(^1\) However, they did not observe a significant pH dependence on the rate. Their value for the ozone-S(IV) rate constant is also listed in Table I.

Erickson and co-workers\(^5\) studied the reaction of ozone-aqueous SO$_2$ over a pH range of <1 to 4. They reasoned that the O$_3$-SO$_2^{2-}$ reaction was much faster that the O$_3$-HSO$_3^{-}$ reaction and used this assumption in their data analysis. They made measurements at 16° and 25°C and obtained an estimate of the activation energies. The rate constants that they obtained are listed in Table I.

Maahs\(^6\) made stopped-flow measurements of the ozone-S(IV) reaction over a range of pH 3.1 to 6.2. Maahs indicated that his results were consistent with those obtained by Erickson et al.\(^5\) Rather than attributing the increase in rate with pH to the O$_3$-SO$_2^{2-}$ reaction, he indicated that the observed pH dependence could be due to hydroxide ion-initiated decomposition of ozone to form the hydroxyl radical. Formation of such an intermediate could cause more than one oxygen atom to be transferred from ozone to sulfate, as observed by Espenson and Taube.\(^7\) He stated that kinetic data alone would be insufficient to discriminate between the two potential processes. Analysis of the data presented in Maahs' Figure 1 indicates that Maahs obtained rates that were about 50% of those from Erickson's study at pH ≥ 4.

Hoigne et al.\(^8\) used the indigo method\(^9\) to determine the reaction rates for ozone with a number of compounds, including S(IV) and nitrite. The ozone-S(IV) reaction was studied over a pH range of 1 to 5.3. The data were analyzed assuming that ozone reacts increasingly rapidly as the S(IV) is deprotonated. The rate constants they obtained for the S(IV) species and some of the other compounds studied are listed in Table I. The value of the rate constant they obtain for the reaction of ozone-sulfite is intermediate between the values obtained by Erickson\(^5\) and Garland.\(^1\) The ozone-nitrite reaction was studied over a pH range of 2 - 5. The rate constant derived was greater than that obtained by Penkett,\(^2\) but agreed well with the study by Garland et al.\(^3\) Their results indicate that nitrous acid reacts much more slowly with ozone than does nitrite.

There is some uncertainty in the ozone-sulfite reaction rate because of the extrapolation from pH 3-5 to higher pH conditions. The reaction rate would be expected to level off at about
pH 8 if the process is a direct reaction between ozone and sulfite. If the reaction involved the ozone-hydroxide reaction, it would be expected to increase steadily as [OH·] increases. It is desirable to measure the ozone-S(IV) reaction at higher pH conditions where SO₃²⁻ predominates. It would also be useful to know what process is responsible for the increase in rate with pH. These three reaction systems have been studied by stopped-flow and pulsed-accelerated-flow (PAF) techniques. Use of the PAF system to study the ozone-S(IV) reaction provided a more direct measurement than the indigo method.

Experimental

Reagents. Buffer solutions of citrate, phosphate, and boric acid, for pH ranges of about 4, 7, and 9, respectively, were prepared by dissolving the analytical reagents in distilled deionized water. The nitrite and iodide solutions were prepared from NaNO₂ and NaI, respectively. The S(IV) solutions were prepared by degassing the buffer solution with Ar prior to addition of either Na₂S₂O₅ or Na₂SO₃. The S(IV) solution was kept under Ar until it was transferred to the instrument syringe for use in rate measurement. The S(IV) concentration in solution was determined by iodimetry. Adjustment of the pH of the solution was done with HClO₄ or NaOH solutions. The pH measurements were made with an Orion 610A digital pH meter and a Corning combination electrode that had been previously calibrated with solutions of ionic strength similar to the solutions under study.

Raman spectra of the reaction mixtures were collected using a Coherent 90-5 argon-ion laser and a Spex 1403 spectrometer controlled by a Spex Datamate data acquisition system. UV-visible spectra of the solutions were taken with Varian Cary 219 and Perkin-Elmer Lambda 9 spectrophotometers.

Ozone was prepared by passing research grade oxygen through a coaxial ozonator tube powered by a luminous sign transformer (9kV, 30mA). Aqueous ozone solutions were prepared by passing the gas stream containing ozone through a glass frit immersed in the solution. The gas phase ozone concentration was adjusted by varying the oxygen flow rate through the ozonator. The aqueous ozone concentration was estimated from literature ozone solubility measurements and determined more accurately by UV absorption. An extinction coefficient of 3000 M⁻¹cm⁻¹ at 260 nm was used in the determination. Measurements of the extinction coefficient for aqueous ozone have been reviewed by Maahs. Since ozone decay rates in alkaline buffers were unacceptably high, ozone solutions for alkaline runs were prepared in unbuffered solutions with ionic strengths matching those in the S(IV) reactant solutions. In these cases, the ionic strength was adjusted using sodium chloride. Once the instruments were conditioned, ozone decay rates of less than 2% per minute were consistently obtained in the
reactant solution during the experiments. Sodium chloride was used to adjust the ionic strength of the S(IV) reactant when desired.

Citrate buffers were used with some of the S(IV) solutions used in stopped flow measurements of the ozone-S(IV) reaction. Citrate absorbs weakly at 260 nm (ε ~ 0.4) and did not interfere with the absorption measurements. Hoigne and Bader\textsuperscript{14a} note that many organic carboxylic acids react with ozone. We found that citrate ion reacts slowly with ozone (k ~ 5 M\textsuperscript{-1} sec\textsuperscript{-1}) at pH > 7. As noted by Hoigne and Bader\textsuperscript{14a}, the dissociated carboxylic acids are more reactive than the acid form, so the effective rate constant at the conditions of our experiments (pH 4 - 5) would be less than the value listed here. The loss due to the ozone - citrate reaction was not significant at any of the conditions used.

Stopped-Flow Measurements. A Durrum D-110 stopped-flow spectrometer (1.88 cm cell path length) interfaced to a Zenith 151 PC with a MetraByte DASH-16 A/D was used for the ozone-nitrite measurements and the low pH (< 5.5) ozone-S(IV) measurements. Data from runs with large values of k\textsubscript{obs} (>60 sec\textsuperscript{-1}) were corrected for mixing using the equation\textsuperscript{15}

\[
1 / k_{\text{obs}} = 1 / k_{\text{reaction}} + 1 / k_{\text{mix}}
\]

where k\textsubscript{mix} = 1700 sec\textsuperscript{-1} for the system used. The NO\textsubscript{2}\textsuperscript{-}-O\textsubscript{3} reaction was studied under pseudo-first order conditions only.

Pulsed-Accelerated-Flow Measurements. To permit measurements of rates faster than those in the range of the stopped-flow technique, the pulsed-accelerated-flow (PAF) method was used.\textsuperscript{10-12} PAF model IV was used in the UV mode for studies of ozone-iodide reaction and ozone-S(IV) reaction at pHs of 6.5 - 9.3. Both pseudo-first order conditions, with [X\textsuperscript{-}]>>[O\textsubscript{3}], and second order conditions were used in the study of the S(IV)-O\textsubscript{3} reaction and the I\textsuperscript{-}-O\textsubscript{3} reaction. The technique is described in more detail elsewhere.\textsuperscript{10-12} Briefly, absorbance measurements of the mixed reactants in the cell are taken while the flow velocity ramps from 12 to 3 m sec\textsuperscript{-1}. At these flow velocities, the mixed solutions have a transit time of 0.8 to 3.3 milliseconds through the PAF cell. The reaction progress variable M(v) is derived from

\[
M(v) = (A_v - A_\infty) / (A_0 - A_\infty) = (1-e^{-y}) / y
\]

where A\textsubscript{v} is the absorbance at flow velocity v, A\textsubscript{\infty} is the final absorbance of the reaction mixture, and A\textsubscript{0} is the initial absorbance of the reactants. Here y is defined as

\[
y = (k_{\text{app}} b) / v
\]

where b is the optical path length in m, v is the flow velocity in m sec\textsuperscript{-1}, and k\textsubscript{app} is the apparent rate constant

\[
1 / k_{\text{app}} = 1 / (k_{\text{mix}} v) + 1 / k_{\text{obs}}.
\]

which is dependent of the mixing rate constant (k\textsubscript{mix}) and the reaction rate constant (k\textsubscript{obs}). When k\textsubscript{app} > 5000 sec\textsuperscript{-1}, there is a linear dependence of M(v) on v

\[
M(v) = 1 / (b k_{\text{mix}}) + v / (b k_{\text{obs}})
\]
Plotting $M/v$ against $v$ gives a slope of $1/(b \text{k}_{\text{obsd}})$, providing a value of $\text{k}_{\text{obsd}}$ and its uncertainty for each run.

Absorbance changes at 260 nm due to the reaction of ozone were in the range of 0.06 - 0.16. All measurements were made at 25°C.

Results and Discussion

Ozone - Iodide Reaction

The reaction of ozone with iodide was using the PAF system to monitor the change in absorption at 260 nm. The reaction products shift the pH of the solution and the initial pH values of 4.8 and 4.5 were calculated from the measured final pH values of 6.4 and 8.0, respectively. The initial ozone concentration was $1.5 \times 10^{-5} \text{ M}$ in the pH 6.4 experiment and $3.4 \times 10^{-5} \text{ M}$ in the pH 8.0 experiment and the initial iodide concentration was $5 \times 10^{-5} \text{ M}$ in both experiments. The reaction mixtures were unbuffered and the measurements were made at 25°C. The reaction was too fast to measure at both conditions. We estimate that the second order rate constant is greater than $4 \times 10^9 \text{ M}^{-1} \text{ sec}^{-1}$. Diffusion limits the rate constant to $7 \times 10^9 \text{ M}^{-1} \text{ sec}^{-1}$. The estimate of the rate constant given by Garland et al,$^1$ $2 \times 10^9$, is significantly less than the estimate that we have obtained. As mentioned by Hoigne et al,$^8$ the most plausible reaction products are $\text{OI}^-$ and $\text{O}_2$.

\[
\text{I}^- + \text{O}_3 \rightarrow \text{OI}^- + \text{O}_2 \tag{6}
\]

The pK$_a$ for hypoiodous acid is 10.7$^{17}$ and the conversion of $\text{OI}^-$ to HOI is rapid.$^{18}$

\[
\text{OI}^- + \text{H}_2\text{O} \leftrightarrow \text{HOI} + \text{OH}^- \tag{7}
\]

HOI rapidly equilibrates with the remaining I$^-$ to form I$_2$,$^{19}$ and I$_2$ and I$^-$ exists in equilibrium with I$_3^-$.$^{20}$

\[
\text{HOI} + \text{I}^- + \text{H}^+ \leftrightarrow \text{I}_2 + \text{H}_2\text{O} \tag{8}
\]

\[
\text{I}^- + \text{I}_2 \leftrightarrow \text{I}_3^- \tag{9}
\]

Using the literature values of the equilibrium constants for reactions (7)-(9), the final concentrations were calculated for the two experimental conditions, shown in Table II. The final absorbances due to the iodine-containing species were calculated using the extinction coefficients$^{21,22}$ listed in Table II. For the pH 6.4 and 8.0 experiments, the final absorbances were found to be 9% and 22% of the initial absorbances, respectively.

Exhaustive ozonation of iodide solutions yielded $\text{IO}_3^-$, which was observed by Raman spectroscopy. The $\text{IO}_3^-$ could be formed by the reaction of ozone with HOI, or by the slow disproportionation of $\text{OI}^-$.

\[
3\text{OI}^- \leftrightarrow 2\text{I}^- + \text{IO}_3^- \tag{10}
\]

From the study of the reactions of ozone with Br$^-$ and HOBr by Haag and Hoigne,$^{16}$ we expect that the reaction of ozone with HOI is slower than the reaction of ozone with I$^-$. Ozonation of
iodine solutions also showed the appearance of $\text{IO}_3^-$. The rate constant that we have obtained indicates the ozone-iodide reaction in seawater is an important loss process for tropospheric ozone.

Ozone - Nitrite Reaction

The reaction was studied over a pH range of 6.1 to 9.9 at 25°C by stopped-flow only.

$$\text{O}_3 + \text{NO}_2^- \rightarrow \text{NO}_3^- + \text{O}_2$$

(11)

In this pH range, no corrections were required for the presence of $\text{HNO}_3$ ($pK_a = 3.0$). The initial ozone concentrations ranged from $7 \times 10^{-6}$ to $4 \times 10^{-5}$ M and the initial nitrite concentrations ranged from $1.0 - 2.5 \times 10^{-4}$ M. The values of the rate constant are shown in Figure 1. Over the limited range studied, the rate showed first order dependence on nitrite concentration, in agreement with earlier studies. The average second-order rate constant that we obtain for the reaction is $3.0 \pm 0.2 \times 10^{-5}$ M$^{-1}$ sec$^{-1}$ at ionic strengths of $\mu = 0.007$ to $0.029$, which agrees well with the values obtained by Hoigne et al and Garland et al at lower pH conditions. No dependence on ionic strength was observed in the range studied. The second order rate constants are independent of pH, so we conclude that radicals generated by the ozone-hydroxide ion reaction do not substantially influence the ozone-nitrite reaction in the range of conditions studied. Nitrate ion was the only product observed in Raman spectra taken of reacted nitrite solutions.

Ozone - S(IV) Reaction

For this reaction, the dependence of the rate on the reactants has been well established by other studies. The rate can be expressed as

$$-d[\text{O}_3]/dt = k [\text{O}_3][\text{S(IV)}]$$

(12)

The ozone-S(IV) reaction was observed over a pH range of 4.0 to 5.2 with the stopped-flow system and pH 6.5 to 9.3 with the PAF system. Since there is good agreement among earlier studies, no effort was made to determine the value for the reaction of ozone with hydrogen sulfite. The ozone concentrations used were $6 \times 10^{-6}$ to $5 \times 10^{-5}$ M and the S(IV) concentrations used were $1 \times 10^{-5}$ to $4 \times 10^{-4}$ M. The pH values, ionic strengths, concentrations, and averaged values of the observed rate constant obtained in the experimental runs are tabulated in Table III. The data were obtained from both the stopped-flow system and the PAF system. The values of $k_{\text{reaction}}$ were corrected for contribution from the ozone-hydrogen sulfite reaction, using a rate constant of $3.2 \times 10^5$ M$^{-1}$ sec$^{-1}$. The corrections were insignificant above pH 7. The values of $k_{\text{corrected}}$ were then used to calculate the rate constant, $k$. In calculating the fraction of S(IV) as $\text{SO}_3^{2-}$, the equilibrium constant for

$$\text{HSO}_3^- \leftrightarrow \text{H}^+ + \text{SO}_3^{2-}$$

(13)

was adjusted for ionic strength. The stopped-flow runs were done with ionic strengths of $\mu = 0.002 - 0.013$ and the PAF runs were done with $\mu = 0.022 - 0.45$. There was no noticeable ionic strength
dependence observed in either the stopped-flow runs or the PAF runs. A plot of log($k_{app}$) versus log([SO$_3^{2-}$]) is shown in Figure 2. The data show a first order dependence on sulfite concentration. There was a fair amount of scatter in the high pH PAF data due to the rapid reaction and the small signal. However, there is no systematic deviation in the value of the rate constant as the fraction of S(IV) as SO$_3^{2-}$ approaches unity. Such a deviation could occur if the ozone-hydroxide ion reaction contributed substantially to the ozone-S(IV) reaction process.$^{25}$ The values of $k_{corrected}$ below pH 4.5 are not considered as reliable as the values obtained at higher pH conditions, in part because the correction applied for HSO$_3^-$ was significantly larger than for the higher pH conditions. A least squares fit to the data from conditions with pH 4.5 and above yields a value of $k_{corrected} = 7.5 \pm 1.8 \times 10^8$ M$^{-1}$ sec$^{-1}$ at [SO$_3^{2-}$] = 1 M, where $k_{corrected} = k$ for the ozone + sulfite reaction. An average of the individually calculated values of $k$ gives a similar value of $7.3 \pm 4.1 \times 10^8$.

Espenson and Taube$^7$ studied the reaction of ozone with SO$_2$(aq) and SO$_3^{2-}$ that were isotopically enriched with O$^{18}$. These studies were done only at very acidic (pH<1) and very alkaline (pH>12) conditions. Their results indicated that more than one oxygen atom was transferred from ozone to the sulfate product. They observed that ozone induced sulfate to slowly undergo oxygen atom transfer with water in the absence of sulfite. They also studied oxygen atom transfer in the ozone-nitrite reaction. In this reaction, they observed the transfer of one oxygen atom to the nitrate product, in agreement with expectations. It is noted that the experimental conditions used by Espenson and Taube which generated higher aqueous ozone concentrations during reaction created larger values of oxygen atom transfer to S(IV). They offer a possible mechanism for the transfer of two oxygen atoms to S(IV) under very acidic conditions, but they do not speculate about a possible process involved with the transfer of two oxygen atoms at high pH conditions.

Under such alkaline conditions, it is possible that hydroxyl radicals could be formed by a process such as

$$O_3 + OH^- \rightarrow O_2^{2-} + HO_2^+$$  \hspace{1cm} (14)  
$$HO_2^- \rightarrow H^+ + O_2^{2-}$$  \hspace{1cm} (15)  
$$O_3 + O_2^{2-} H_2O \rightarrow OH^- + OH^- + 2O_2$$  \hspace{1cm} (16)

The reaction of OH$^-$ with S(IV) could generate additional radicals which could effect greater that unitary oxygen atom transfer from ozone to S(IV). The O$_2^{2-}$ formed by reaction 16 could react with S(IV) to produce the same result. However, at moderate OH$^-$ concentrations, the free radical contribution would be expected to be much smaller.

With solution conditions at moderate pH (4.1 - 9.3), where [S(IV)] > [OH$^-$], it is expected that the direct reaction would predominate, since the rate of the ozone-hydroxide reaction is significantly less that the ozone-S(IV) reaction.$^{26}$ Kinetic studies of the ozone-
S(IV) reaction have been, by and large, reasonably consistent and no fractional order dependence on [S(IV)] has been reported.2-6,8 The reaction of ozone with sulfite would most plausibly involve nucleophilic attack of sulfite on ozone.

\[
\text{O}_3 + \text{SO}_3^{2-} \rightarrow \text{O}_3^- + \text{SO}_3^{4-} \tag{18}
\]

If this pathway was important, a significant amount of dithionate would be present in the reaction products from the reaction28,29

\[
\begin{align*}
\text{SO}_3^{2-} + \text{SO}_3^{2-} & \rightarrow \text{SO}_3^{2+} + \text{SO}_3^{4-} \tag{19a} \\
\text{SO}_3^{2-} + \text{H}_2\text{O} & \rightarrow 2\text{H}^+ + \text{SO}_4^{2-} \tag{19b} \\
\end{align*}
\]

The branching for reaction 19 was studied by Waygood and McElroy.28 The product distribution was checked by Raman spectroscopy. Ozone was trapped on silica gel at dry ice temperature and the oxygen was removed by purging with nitrogen. The silica gel was warmed to about -50°C, and the flow of N2 and O3 was directed through a solution of 0.5 M SO3^2-. There was no detectable S2O6^2- in the Raman spectra of the oxidized solution, which indicated that less than 1% of the SO3^2- was converted into S2O6^2-. We conclude that ozone-S(IV) reacts primarily by O atom transfer under the conditions studied.

The ozone-cyanide reaction is one in which free radicals have been implicated in the reaction process. The reaction of ozone with cyanide has been studied by Gurol and Bremen30 and the reaction displays behavior typical of free radical involvement. At high pH (>9), the rate shows fractional order dependence on [CN^-]. The addition of tert-butyl alcohol or other free radical scavengers brought the [CN^-] order dependence close to unity. The reaction displays first order dependence on [CN^-] at neutral pH conditions where the ozone-hydroxide ion reaction would be less important. Gurol and Bremen proposed a mechanism involving both a
direct reaction of ozone with cyanide and a reaction of hydroxyl radical with cyanide. They propose that \( \text{OH}^\cdot \), the hydroxyl radical, is formed indirectly from the reaction of ozone with hydroxide, \( \text{OH}^- \), as indicated in reactions (14) - (16), above. Our studies generally were at pH 9 or lower and the reactions did not appear to involve a radical pathway.

**Nucleophilicity**

The Swain-Scott relationship,\(^{31-33}\) which correlates rate constants with the nucleophilicity (\(n\)) of anions and the sensitivity (\(s\)) of the reaction site, was derived for nucleophilic attack at carbon.

\[
\log \left( \frac{k}{k_0} \right) = sn 
\]

There are several nucleophilic scales in use in the literature.\(^{31-33}\) The one used here is based on the scale presented by Swain and Scott.\(^{31}\) In such situations, \(s\) is typically 1 ± 0.5. More recently, the relationship has been applied to \( \text{Cl}^+ \) transfer reactions of \( \text{HOCI} \).\(^{12,34}\) In the case of nucleophilic attack at chlorine in \( \text{HOCI} \), \( s = 4.7 \pm 1 \), indicating that these reactions are much more sensitive to the nucleophilic strength of the anions than are the reactions of carbon. Using the results of this study and other studies of ozone reactions, we have applied the Swain-Scott relationship to O atom transfer reactions of ozone. The nucleophilic anions and their second-order rate constants for reaction with ozone are listed in Table IV along with their nucleophilicity. Sulfite, hydroxyl and the halide ions are generally believed to react with ozone by O atom transfer.\(^{8,26}\) The reaction mechanisms for the other compounds in Table IV, \( \text{HS}^- \), \( \text{NH}_3 \), and \( \text{NH}_2\text{OH} \), have not been established. However, it is plausible that they could also proceed by O atom transfer. If the \( \text{HS}^- \) - ozone reaction is analogous to the \( \text{HO}^- \) - ozone reaction,\(^{26}\) \( \text{HSO}^- \) would be the initial product. The ultimate oxidation product of \( \text{HS}^- \) is believed to be sulfate.\(^{35}\)

Ammonia and hydroxylamine are ultimately oxidized to nitrate,\(^8\) although the mechanism has not been established. These reactions could plausibly proceed via O atom transfer. If ammonia forms \( \text{NH}_3\text{O} \), it could rearrange to \( \text{NH}_2\text{OH} \), which reacts more quickly with ozone than ammonia. A plot of the values of \( \log k \) versus nucleophilicity from Table IV is shown in Figure 3. The data for the reactions known to proceed by O atom transfer are shown as squares and the line is a least squares fit to these points, and has a slope of 6.2 ± 0.6. This slope is somewhat higher than the value of \( s = 4.7 \) obtained by Gerritsen and Margerum\(^{34}\) for the \( \text{HOCI} + X^- \) reactions. It is noteworthy that the values for \( \text{HS}^- \), \( \text{NH}_3 \), and \( \text{NH}_2\text{OH} \), shown as triangles, also lie close to the line derived from the other reactions.

We conclude that the reactions of iodide, sulfite, and nitrite with ozone proceed by O atom transfer and do not show evidence of radical-mediated reactions at the conditions studied. The ozone - S(IV) reaction results support the conclusions of Hoigne et al\(^8\) from their
measurements using the indigo method. The rate constants for nucleophile-ozone O atom transfer reactions show good correlation with the nucleophilicity values in the literature.

Acknowledgment. This work was supported by the Assistant Secretary for Fossil Energy, Office of Coal Utilization Systems, U.S. Department of Energy under Contract No. DE-AC03-76SF00098 through the Pittsburgh Energy Technology Center, Pittsburgh, PA. I would like to thank Dale W. Margerum (Department of Chemistry, Purdue University, West Lafayette, IN 47907) for the use of the stopped-flow and PAF instruments and many helpful discussions on kinetics of ozone reactions and pointing out the nucleophilicity-rate relationship. I would also like to acknowledge the assistance of Sam W. Evetts (Purdue University Chemistry Department) in acquiring and analyzing the data.

[b] - adjusted for different scale
Figure Captions

Figure 1. Values of the rate constant for the ozone-nitrite reaction obtained by stopped flow, shown as a function of pH. The average value for the rate constant is $3.0 \pm 0.2 \times 10^{-5} \text{ M}^{-1} \text{ sec}^{-1}$.

Figure 2. A plot of log ($k_{app}$) from PAF and stopped-flow measurements after correction for the HSO$_3^-$ - O$_3$ reaction as a function of log([SO$_3$$^{2-}$]). The slope is one, indicating first order dependence on [SO$_3$$^{2-}$]. The intercept provides the value of k for the reaction of ozone with sulfite.

Figure 3. Swain-Scott plot of log k for the reaction of ozone with Cl$^-$, Br$^-$, OH$^-$, SO$_3$$^{2-}$, and I$^-$ (squares) versus the nucleophilicity of the anions. The values of log k for the reaction of ozone with HS$^-$, NH$_3$, and NH$_2$OH are also shown (triangles). The slope is $6.2 \pm 0.6$. 
Figure 1

$K (\text{Mole/sec} \times 10^6)$ vs pH
