ABSTRACT:

History of present illness: A 20-year-old female on day nine of amoxicillin for a recent diagnosis of pharyngitis presented to the emergency department with a complaint of rash for two days. The patient’s clinical course started two weeks prior and included fever, tonsillar exudates, and fatigue. Initial vitals were temperature of 37.6°C, blood pressure 122/82, heart rate 135, respiratory rate 18, and oxygen saturation 100% on room air.

Significant findings: Her physical exam was significant for bilateral tonsillar exudates, cervical lymphadenopathy, and a morbilliform rash that included the palms (Figure 1-4). Laboratory testing was significant for white blood cell (WBC) count of 16.5 thous/mcl with an elevation in absolute lymphocytes of > 10 thous/mcl. The monospot and EBV (Epstein-Barr virus) panel were positive.

Discussion: Infectious mononucleosis (IM) is a clinical syndrome characterized by a triad of fever, tonsillar pharyngitis, and lymphadenopathy, and is most commonly associated with primary Epstein-Barr virus (EBV) infection. The incidence of IM in the United States is 500 cases/100,000 person-years, with the highest incidence between ages 15 to 24 years. EBV transmission occurs predominantly through exposure to infected saliva, with an incubation period of 30 – 50 days. The majority of patients with IM recover without apparent sequelae and most clinical and laboratory findings resolve by 1 month after diagnosis. Cervical adenopathy and fatigue may resolve more slowly ( ≥ 6 months for fatigue). IM may be associated with several acute complications including splenic rupture (0.5 – 1%) and airway obstruction (1%). A morbilliform rash occurs in up to 95% of patients with IM who are treated with beta-lactam antibiotics for presumed group A streptococcal infection. Diagnosis is typically made in the setting of the clinical syndrome combined with laboratory test to detect antibodies to certain EBV-associated antigens. Primary EBV infection induces the activity of a heterogeneous group of circulating heterophile (IgM) antibodies directed against viral antigens that cross-react with antigens found on sheep and horse red cells. Rapid (monospot) tests for these heterophile antibodies are used to screen patients for infectious mononucleosis. In the presence of mononucleosis symptoms, a positive heterophile antibody tests has a sensitivity of approximately 85% and a specificity of approximately 94% for the diagnosis of infectious mononucleosis. Management is primarily supportive and avoidance of sports for at least 3 weeks is generally recommended.

Topics: Infectious mononucleosis, pharyngitis, morbilliform rash.
