Significant progress has been made at the biochemical and genetic levels in our understanding of how some environmentally and medically important obligate anaerobes can survive temporarily a sudden exposure to oxygen. However, our understanding at a cellular molecular level of the actual capacity and mechanisms of how these anaerobes survive remains incomplete (7). The cellular chemical environment fundamentally comprises the nexus between external stimuli and internal biochemical regulatory mechanisms—and affects many properties of cellular adaptive response as well. Determining this transient chemical environment in vivo is critical for achieving a more coherent understanding of how some obligate anaerobes adapt to the extreme fluctuations in oxygenation. Such knowledge is seldom complete because it is difficult to make in vivo molecular measurements without disturbing cells. In almost all previous studies, cellular chemistry of oxygen-stress adaptive response has been determined by measuring intermediate reaction products in cell extracts taken at selected times (8–10); notably, ongoing changes within a live cell are seldom measured directly. The instability of many of the intermediates greatly complicates measurements of cell extracts and their analyses.

Here, we present results of our using the non-invasive synchrotron radiation-based Fourier transform infrared (FTIR) spectromicroscopy approach (11) to determine the cellular chemical environment by continuously monitoring the dynamics of hydrogen bonding in cellular water in vivo. More than 70% of the cellular constituents are highly polar water molecules, and their hydrogen bonding is a useful reflection of the cellular chemical environment because it responds “instantaneously” to ions and other species in their surroundings (12, 13). The infrared spectrum of OH stretch vibrations has been widely used to characterize the dynamics of hydrogen-bonding structures in pure water (13–23). These infrared spectroscopy studies have revealed distinct shifts in vibration frequencies and changes in spectral shapes and intensities induced by ions and small molecules (e.g., radicals, small organic acids, and hydrogen gas) in water; similar small molecules are expected to be in cellular water during functional metabolism of the oxygen stress adaptive response.

In this study, we investigated the dynamics of cellular chemical environment in a model oxygen-stress adaptive response system, namely that of the strictly anaerobic sulfate-reducing bacterium Desulfovibrio vulgaris Hildenborough during transient exposure to air. Sulfate-reducing bacteria are of particular interest because of their importance in cycling and transformation of essential nutrients and minerals (24, 25) and their links to different pathogenesis (26, 27) in environments where extreme fluctuations in oxygen concentrations occur. Among sulfate-reducing bacteria, genome sequencing has shown that D. vulgaris has developed well-defined protective enzymatic oxygen-defense systems (5, 24). The bacteria can even survive very high levels of oxygen in their natural environment (28, 29), but the mechanism remains elusive. We demonstrate here that molecular information provided by real-time, in vivo FTIR measurements of the transient cellular chemical environment is key to advancing fundamental understanding of how these obligate anaerobes adapt to extreme changes during air exposure, by providing direct observations of molecular events measured in the same cells over time.

Results and Discussion

Identifying D. vulgaris Cells That Can Survive Temporarily in Atmospheric Oxygen. We first conducted microscopic and spectroscopic analyses to establish, at a whole cell level, the molecular identity of D. vulgaris cells that can survive transient exposure to atmospheric oxygen. This identity enabled us to select the appropriate cells for real-time FTIR measurements of oxygen-stress survival response. Fluorescence microscopy images of two nucleic acid stains show that most stationary-phase (but not exponential-phase) D. vulgaris can survive short-term oxygen exposure. Subsequent electron microscopy images reveal that stationary-phase (but not exponential-phase) D. vulgaris accumulates polyglucose (Figure 1A) and stores elemental sulfur particles (Figure 1B). Their FTIR spectrum shows...
such alterations compared to those with substantially more damage suggests controls. Different colors represent different viability experiments. 

**Fig. 1.** Microscopic and spectroscopic analyses of Desulfovibrio vulgaris. (A) Left, typical infrared absorption spectra of stationary-phase (red) and exponential-phase (blue) D. vulgaris; Right, transmission electron microscopy (TEM) images of thin sections poststained by the periodic acid thiosemicarbazide-osmium (PATO) method (S1) show intracellular polyglucose granules (arrows) in stationary-phase but not exponential-phase D. vulgaris. (B) Left, cryo-electron microscopy (Cryo-EM) image of a stationary-phase cell containing a large, dense ball; Right, energy dispersive X-ray analysis of freeze-dried cells with (blue) and without (red) such structures. Spectra from areas such as marked by the blue circle in the left image show that the particle contains mainly sulfur. (C) The growth of D. vulgaris after exposure to air. Note the approximate 20-h lag-time (compared to controls). Different colors represent different viability experiments. (D and E) Cryo-EM (Left) and TEM/PATO (Right) images of D. vulgaris after exposure to air for hours show changes in cell membranes, variation in periplasmic space, motiled appearance of cell contents and decreased number of polyglucose granules compared to the unexposed cell in Figs. 1 A and B. The frequency of cells showing such alterations compared to those with substantially more damage suggests that these cells were still alive. (Scale bar, 0.2 μm.)

**FTIR Measurement and Analysis Considerations.** Mid-infrared photons emitted from the synchrotron at the Advanced Light Source in the Lawrence Berkeley National Laboratory (CA, USA) were focused through a 15-μm aperture onto a monolayer of stationary-phase D. vulgaris cells maintained inside an oxygen-free humidified microscope stage chamber (Fig. 2A). In Fig. 2B is an FTIR spectrum typical of small groups of stationary-phase D. vulgaris cells, showing well-resolved vibration bands from polyglucose (30) and other biological macromolecules (31) superimposed on the broad continuum absorption features of the aqueous liquid. To minimize inter-experimental uncertainties, only cells that exhibited spectral features within one standard deviation of the mean (Fig. 2B) were selected for the oxygen-stress adaptive response experiments and the controls. We used the spectrally integrated absorption intensity of the polyglucose α-C-OH band between 1,055 and 1,045 cm⁻¹ and the glycosidic linkage vibration (νC-O-C) at 1,175 cm⁻¹ (30). These cells can survive air exposure for hours and resume growth when returned to anaerobic conditions (Fig. 1C), despite significant changes in cellular structures and contents (Figs. 1 D and E).

**Fig. 2.** FTIR measurement setup. (A) Schematic description of the experimental measurement setup. An all-reflective optics infrared microscope focuses the interferometer-modulated synchrotron infrared microbeam through a 15-μm aperture onto a monolayer of live D. vulgaris. The reflected signals are collected and sent to the detector. The optical density of this thin film is typically 0.05 at the band dominated by the combined water-bending vibration and libration at ~2,100 cm⁻¹. This is an equivalent to a water-film of ~1.5-μm thick. This experimental system enables FTIR measurements with a temporal resolution of every minute for up to 4 h; a different experimental arrangement would be needed to investigate changes on a finer temporal scale or a longer duration. (B) Spectral variations in polyglucose-accumulated stationary-phase D. vulgaris in anaerobic atmosphere. The spectrum shows the polyglucose C=O-H bond between 1,055 and 1,045 cm⁻¹. Within the hydride-OH dominated stretch region between 1,900 and 3,800 cm⁻¹ are a broad OH stretching (νOH) band between 2,900 and 3,700 cm⁻¹, the combined water OH bending and libration modes (νOH + ν3 HOH) at ~2,100 cm⁻¹. Absorption bands between 1,800 and 900 cm⁻¹ are dominated by vibration motion of biopolymers of D. vulgaris. Averaged spectrum (black line) ± 1 standard deviation (gray lines); n = 50.

**Real-Time FTIR Spectromicroscopy of Oxygen-Stress Adaptive Response in Live D. vulgaris.** We monitored cells first under anaerobic conditions and then exposed to air. The measurements are shown in Figs. 3 and 4, respectively, with comparisons shown in Figs. 4C and D. The experiments proceeded as follows. We first made real-time FTIR measurements on a monolayer of D. vulgaris inside the oxygen-free humidified microscope stage chamber [hereafter D. vulgaris (+polyGr-air)] every 5 min for 240 min without interruption. Fig. 3A shows the real-time FTIR spectra. An easy way to analyze and understand the time-difference spectra is to make a 2-dimensional time-frequency contour plot of the difference spectra in the hydride-OH stretch region, as shown in Fig. 3B (negative values are shown in dark blue) with difference spectrum snapshots below. The plot shows, for t < ~50 min, positive bands at ~3,190 cm⁻¹, 3,645 cm⁻¹, and a shoulder feature at 3,745 cm⁻¹. These frequencies are in the νOH regions of H-bonding structures of water molecules surrounded by hydrogen gas H₂ (i.e., hydrogen hydrates) (14). This increasing positive behavior suggests a temporarily enhanced hydrogen gas production event, which is consistent with the central metabolism of D. vulgaris under anaerobic conditions (24, 35). This spectral information is taken as reference.
which can result from a contribution due to periplasmic oxygen reduction to water by cytochrome c₃ with existing intracellular H₂ (36, 37), since we observed H₂ was produced during anaerobic metabolism (see Fig. 3B). Then, from \( t > 0 \) to \( t = 50 \) min, there is a substantial decrease in the polyglucose band intensity (Fig. 4D) but little change in the water band intensity (Fig. 4C). Polyglucose oxidation by D. vulgaris(+)polyG;+air) may contribute to this substantial polyglucose decline. We performed an independent carbohydrate analysis of similar D. vulgaris exposed to humid air which showed a more than 30% decrease in carbohydrate in cells in the first hour of air exposure. At \( t > 50 \) min, the water band intensity increases abruptly (Fig. 4C); the rate of polyglucose disappearance slows at later times (\( t > 100 \) min) (Fig. 4D). For an elucidation of the mechanism(s) underlying this behavior, it is crucial to analyze the time-difference spectra in the hydride-OH region carefully.

As seen in Fig. 4B, between \( t > 0 \) and \( t = 50 \) min there are 2 large increasingly positive absorption bands, and the band positions are in the region of the \( \nu \text{OH} \) of a water molecule H-bonding with a carboxylic acid or carboxylate: the band between \( \nu = 3,500 \) and \( 3,300 \) cm\(^{-1}\) corresponds to the \( \nu \text{OH} \) of a water molecule H-bonding loosely with the alcohol OH group (19), and the band between \( \nu = 3,000 \) and \( 2,600 \) cm\(^{-1}\) corresponds to the \( \nu \text{OH} \) of a water molecule tightly H-bonded to a carboxyl (C = O) group (19). Polyglucose oxidation by desulfovibrios to acetate (a 2-carbon carboxylate) (9, 38) may contribute to these 2 large increasingly positive bands. The significant increase with time in the peak intensity of acetate observed (labeled as green circles in Fig. 4E), and the concurrent decrease in the polyglucose band intensity (inverted green triangles in Fig. 4D) suggest that D. vulgaris(+polyG;+air) oxidizes polyglucose rapidly to acetate, which it initially accumulates.

The noticeable disappearance of these 2 acetate \( \nu \text{OH} \) bands at \( t > 50 \) min (Fig. 4B) implies disappearance of acetate (see also green circles in Fig. 4E), even though polyglucose degradation continues for a time (green inverted triangles in Fig. 4D). Meanwhile, a new broad \( \nu \text{OH} \) band begins to appear at frequencies between \( \nu = 3,750 \) and \( 3,550 \) cm\(^{-1}\) (blue triangles in Fig. 4E). The most likely explanation of this co-occurrence at \( t > 50 \) min (compare the green circles for acetate and the blue triangles for CO₃ in Fig. 4E) is a conversion of acetate to CO₂ (with increasing water content in cells; see inverted green triangles in Fig. 4C). This co-occurrence suggests an onset of an adenosine triphosphate (ATP)-generating pathway, possibly via C₁ intermediates (40). Other pathways would be the tricarboxylic acid (TCA) cycle or the glyoxylate shunt, although they are less likely to occur since D. vulgaris lacks the genes for the production of key enzymes required in these cycles (24, 41).

Also appearing at \( t > 50 \) min is an intense positive \( \nu \text{OH} \) band between \( \nu = 3,200 \) and \( 3,030 \) cm\(^{-1}\) (Fig. 4B), which is typical of a water molecule that forms a strong I₂ bond with species such as the superoxide anion (16), hydroxyl radicals (15, 17, 18), and the hydroperoxyl radicals (22). This suggests that the formation of ROS exceeds their removal by the protective enzymes and other mechanisms in D. vulgaris(+)polyG;+air) at this time (red squares in Fig. 4E).

At \( t = 70 \) min, a striking new \( \nu \text{OH} \) band begins to appear between \( \nu = 3,630 \) and \( 3,520 \) cm\(^{-1}\) in the spectral region of water molecules H-bonded to sulfate anions (23). Its notable persistence in intensity (pink hexagons in Fig. 4E) is consistent with previous observation that D. vulgaris can oxidize its accumulated elemental sulfur and other reduced sulfur compounds (42, 43). It has been suggested that the oxidation is by means of an ATP/adenyl sulfate (ATP/APS) pathway that couples the sulfate ion formation with oxygen reduction to water (42, 43). Considering that sulfate formation is an acidification reaction that produces protons (H⁺), it is interesting that this acidification process coincides with the disap-

**Fig. 3.** FTIR analyses of D. vulgaris in anaerobic atmosphere. (A) Real-time FTIR spectra of polyglucose-accumulated stationary-phase D. vulgaris in an anaerobic environment. Sequential spectra are offset vertically for clarity. Since all spectra are derived using air as a reference, the negative spectral feature at \( \nu = 2,348 \) cm\(^{-1}\) (associated with lack of atmospheric CO₂) is a marker for an air-free condition throughout this investigation. (B) FTIR time-difference spectra in the hydride-OH dominated stretch region. Top, a 2-dimensional frequency-time contour plot (the time-difference intensities are normalized to the maximum); Bottom, snapshots for selected different time points. Positive bands (labeled as \( \nu \text{OH(water-H₂)} \)) arise from \( \nu \text{OH} \) of water molecules forming H-bonding with H₂ (\( \nu = 3,190 \), \( \nu = 3,640 \), and \( \nu = 3,745 \) cm\(^{-1}\)). The straight black line marks that difference absorbance \( = 0 \).

Using the same methodology, we then examined the survival of similar D. vulgaris [D. vulgaris(+)polyG;+air)] in atmospheric oxygen. We began by making FTIR measurements of D. vulgaris in an anaerobic atmosphere for 30 min before introducing sterile air at \( t = 0 \). Unlike the quiescent FTIR spectra from D. vulgaris(+)polyG;+air) (Fig. 3A), these spectra show dramatic variations over time (Fig. 4A). The 2-dimensional time-frequency contour plot of the time-difference spectra in the hydride-OH stretch region is shown in Fig. 4B with time-difference spectrum snapshots below.

Spectrally integrated absorption intensities of water and polyglucose bands are shown in Figs. 4C and D. Under anaerobic conditions, the intensity of the combined water OH bending and libration modes (blue circles in Fig. 4C) and the polyglucose C–OH vibration band (blue circles in Fig. 4D) exhibit little change, but after air exposure they exhibit a multiphasic pattern. There is a small but reproducible “jump” in the water band intensity (green inverted triangles in Fig. 4C) upon air exposure,
Several hundreds of cm\(^{-1}\) toward lower frequencies, and reflects an initial disordered ensemble of many different OH stretching vibration modes. The ROS formation continued to exceed their removal with air exposure time, as demonstrated by the monotonically increasing intensity and gradual red-shifts of the vibration modes (centered at \(\approx 3,100\) cm\(^{-1}\)) initially to \(\approx 3,050\) cm\(^{-1}\) at later times). The immediate positive feature detected at \(\approx 3,570\) cm\(^{-1}\) (the red trace in Fig. 5 Lower) is within the spectral region of water molecules H-bonded to sulfate anions (23). This small positive value is consistent with our earlier observation that \(D. vulgaris\) in exponential phase accumulates little elemental sulfur. Little growth was detected when these \(D. vulgaris\) were returned to oxygen-free conditions.

**Conclusions and Implications.** Our interpretation of the \(\nu\)OH bands in the FTIR time-difference spectra along with the time-course of the polyglucose \(\nu\)C-OH and the water (\(8\)OH + \(\nu\)HOH) band intensities is summarized in Fig. 6. Considering the complexity of a living bacterial system, the consistency of the spectral features and the agreement with the putative events of oxygen-stress adaptive response is striking. We have thus demonstrated both the efficacy of using the hydrogen bonding in water of living cells to profile intracellular chemical environment and their significant consequences for understanding functional metabolic controls in “obligate” anaerobic bacteria that can survive oxy-
molecules H-bonding with hydroxyl and hydroperoxyl radicals [labeled as OH...ROS]. In cases where transient chemistry is dominated by ions, the experimental design and interpretation of the data should be straightforward in cases where transient chemistry is dominated by ions or other small chemical species. Even in more complex cases, we anticipate that the interpretation of infrared spectroscopic data in terms of the hydrogen-bonding structure of cellular water will open the door to investigations of chemical and molecular structural changes in living bacteria and other cellular systems over the course of their stress-adaptive response.

Materials and Methods

Bacterial Strains and Culture. Desulfovibrio vulgaris Hildenborough (ATCC 29579) was obtained from the American Type Culture Collection. All D. vulgaris used in this study were cells of second passage grown on a defined lactate sulfate medium (LS4D medium) soft agar plate (1.0% w/vol). The LS4D medium was based on Postgate's medium C. To prepare stationary-phase D. vulgaris population, we grew D. vulgaris (at high cell density) anaerobically on soft LS4D agar until the growth of some bacterial colonies reached confluence. Most cells from the confluent colonies exhibited infrared spectral characteristics typical of polyglucose-containing D. vulgaris (red trace in Fig. 1A). To prepare exponential-phase D. vulgaris population, we grew D. vulgaris (at low cell density) anaerobically on LS4D agar until the growth of bacterial colonies first became visible. Cells from these microcolonies mostly did not exhibit infrared spectral characteristics typical of polyglucose-containing D. vulgaris (blue trace in Fig. 1A).

Preparation of D. vulgaris Monolayers. To ensure that each D. vulgaris cell in the FTIR experiment was in contact with atmospheric oxygen, we prepared μm-thick layers of D. vulgaris. We transferred D. vulgaris cells onto a LS4D-treated gold-coated glass wafer. An additional mist of liquid LS4D was applied to the replica-printed wafer, which was then incubated for an additional 24 h to facilitate migration of mobile cells to form monolayers on the LS4D-treated gold-coated glass wafer under suitable conditions. To assess the morphological quality of the monolayers, the wafer was placed in a custom microscope stage chamber (filled with nitrogen gas), and was observed by oblique illumination microscopy. Before the FTIR experiment, any excess (moving) LS4D medium was removed by wicking.

High-Resolution FTIR Spectroscopy. We built a high-humidity microscope stage chamber (Fig. 2A) that allows one to maintain a constant μm-thick layer of live D. vulgaris, overcoming the water interference during high-resolution FTIR spectroscopy measurements. All measurements were performed with a Nicolet Magna 760 FTIR bench and a Nicolet Nic-Plan IR microscope equipped with a microscope stage chamber at the infrared beamline of the Advanced Light Source (Lawrence Berkeley National Laboratory, CA, USA; http://infrared.als.lbl.gov/). Each spectrum represents an average of 84 scans over a wavenumber range of 4,000 to 650 cm⁻¹ at a spectral resolution of 4 cm⁻¹ with an absorption peak position accuracy of 1/100 cm⁻¹. As the beam current of the synchrotron decreases with time between electron refills (9 h), the beam intensity decreases proportionally. Appropriate baseline removal took this into account. All data processing was performed using Thermo Electron's Omnic 7.2 (http://www.thermo.com/) and Origin 6.0 (http://www.originlab.com/). Time-difference spectra are calculated [using Thermo Electron's Omnic 7.2 software (http://www.thermo.com/)] from experimental spectra after subtraction of culture medium/liquid water absorbance (46). The time-difference spectra calculation was performed using the water factor approach (47) to minimize absorbance of the water continuum. Analysis of time difference spectra is described in the main text.

Fig. 5. Typical FTIR difference spectra show reactive oxygen species (ROS) build-up in polyglucose-deficient exponential-phase D. vulgaris. Top, a 2-dimensional frequency-time contour plot (the time-difference intensities are normalized to the maximum); Bottom, snapshots for selected different time points. The peak centered at ~3,100 cm⁻¹ and other local maxima centered at ~2,904 cm⁻¹ and 2,810 cm⁻¹ are at frequencies typical of the OH of water molecules H-bonding with hydroxyl and hydroperoxyl radicals [labeled as OH(water...ROS)]. The feature at ~3,570 cm⁻¹ is at a frequency typical of the OH of water molecules H-bonded to sulfate anions. Yellow dots mark the red-shift of ~75 cm⁻¹ of OH of hydroxyl radical band peak. The dashed line marks that difference absorbance ~ 0. The positive absorption feature at ~2,360 cm⁻¹ is from CO₂ in air.

Fig. 6. A summary of the evolving cellular chemical environment and possible survival mechanisms inside the same living D. vulgaris during its transient oxygen-stress and adaptive response, as revealed by the real-time high-resolution synchrotron FTIR measurements and analyses. Polyglucose is labeled as PolyG.
Carbohydrate Analysis. Cell pellets were collected from air exposure experiments and were re-suspended in 1 mL of 0.7% NaCl (wt/vol). Protein concentrations were determined with the Lowry assay using BSA (Pierce Bioc hemicals) as the standard (48). Hexas sugars were measured using the colorimetric cysteine-sulfuric acid method (49) with glucose as the standard.

Live/Dead Fluorescence Microscopy for Distinguishing Live and Dead Bacteria. The LIVE/DEAD BacLight bacterial viability kit (Molecular Probes) in combination with a fluorescence microscopics (Zeiss) was used. Here, cells were exposed to air for t = 0, 30, 240, and 480 min; and the level of internalized red fluorescing propidium relative to green fluorescing SYTO9 allowed for differentiation between D. vulgaris with intact cytoplasmic membranes (bright green) and D. vulgaris with damaged cytoplasmic membranes (red/yellow) (50).

Electron Microscopy. For conventional TEM/PTO samples, D. vulgaris were fixed, embedded, thin sectioned, and post-stained by the periodic acid thiosemicarbazide-osmium (PATO) exactly as previously described (51). Prepara tion and imaging were conducted at the Robert D. Ogg Electron Microscope Lab at the University of California, Berkeley, CA (http://em-lab.berkeley.edu/ EML/index.php). Cryo-EM samples were made by placing 5-µl aliquots of the D. vulgaris suspension onto lacy carbon grids (Ted Ted Pella 01881) that were pretreated by glow-discharge, then blotting and plumping into liquid ethane. Images were recorded on a JEDL-3100 electron microscope operated at 300 kV by a Gatan 975 CCD camera at a magnification of 30,000×. Samples to be used for EDX analysis were freeze-dried in the microscope's airlock and then examined in an FEI CM-200 microscope equipped with a Link EDX detector.

Re-Growth Experiment. The re-growth experiments were to obtain growth curves of control (anaerobic) versus air-exposed cells when returned to oxygen-free conditions. Stressed and control cells grown from the oxygen stress experiment were removed from the culture bottles after 24 h of either N2 or air purge. Ten microliters culture was added to 100 µL LSAD medium in wells of an empty microplate. Eight replicate wells were used for each culture. Cells were incubated in the Omnilog (Biolog) anaerobically at 30 °C for 100 h. Increase in cell density was quantified by recording increased opacity caused by the accumulation of FeS precipitates. The Omnilog uses a scanning technology, which is analogous to a turbidity measurement, to record the increase in density in Omnilog (OL) units.

ACKNOWLEDGMENTS. We thank Dr. K. McDonald and Ms. R. Zalpuri at the Robert D. Ogg Electron Microscope Lab, UC Berkeley, and Dr. Z. Lee at the National Center for Electron Microscopy, Lawrence Berkeley National Laboratory, for technical assistance; Ms. D. Joyner for technical assistance; Drs. H. Bechtel, Z. Hao, J. Jansson, C. Jansson, M.C. Martin, W. McKinney and J. Zhou for discussions and comments on this work and the manuscript.
