The Gregory-Kershaw-Inness (GKI) parameterization of convective momentum transport, which has a tunable parameter $C$, is shown to be identical to a parameterization with no pressure-gradient force and a mass flux smaller by a factor of $1 - C$. Using cloud-resolving simulations, the transient matrix for momentum is diagnosed for deep convection in radiative-convective equilibrium. Using this transient matrix, it is shown that the GKI scheme underestimates the compensating subsidence of momentum by the factor of $1 - C$, as predicted. This result is confirmed using a large-eddy simulation.

1. Introduction

As clouds convect, they transport horizontal momentum in the vertical. This process is referred to as convective momentum transport (CMT), and several schemes for parameterizing its effect have been proposed (e.g., Schneider and Lindzen 1976; Zhang and Cho 1991; Gregory et al. 1997) for use in general circulation models (GCM). It has been shown that the choice of CMT scheme can have a significant impact on both the mean climate (Wu et al. 2007; Richter and Rasch 2008; Kim et al. 2008) and the interseasonal variability (Neale et al. 2008; Kim et al. 2008). This paper is motivated by this demonstrated impact of CMT on climate simulations and the uncertainty surrounding how to parameterize it.

It has been known for many years that organized convective systems, such as squall lines, can intensify existing shear by transporting momentum upgradient (Moncrieff and Miller 1976; LeMone 1983; Moncrieff 1992). These systems have been studied using both observations (e.g., Sanders and Emanuel 1977; Lin et al. 1986) and numerical simulations.
(e.g., Moncrieff and Miller 1976; Lafore et al. 1988). In contrast, unorganized convection tends to transport momentum downgradient (Lemone et al. 1984), but there is no consensus on how to parameterize this process. In this paper, we will study CMT in unorganized convection with the aid of a cloud-resolving model, which has proven to be a useful tool in the study of momentum transport (e.g., Soong and Tao 1984; Tao and Soong 1986; Mapes and Wu 2001; Robe and Emanuel 2001; Zhang and Wu 2003; Lane and Moncrieff 2010). The goal is to learn how best to parameterize CMT in general circulation models.

Clouds and the environment exchange horizontal momentum through two mechanisms. The first is the physical exchange of mass via convective entrainment and detrainment. In the bulk-plume equations, the horizontal force induced by this exchange is uniquely specified by the entrainment and detrainment rates. The second mechanism is the horizontal pressure force, which relaxes the cloud momentum and environmental momentum towards one another by equal and opposite measure. Here, we consider two schemes that differ in their treatment of the pressure-gradient force.

The first approach represents the pressure force as some function of the difference in horizontal velocity between the cloud and the environment,

\[ F = F(v - v_c) \quad \text{(DL)}, \]

where \( v \) and \( v_c \) are the environmental wind and cloud wind, respectively. We will refer to this type of parameterization as a drag-law (DL) scheme. Drag-law schemes have been used in the modeling of momentum transport for many decades (e.g., Malkus 1952; Newton and Newton 1959; Hitschfeld 1960; Newton 1966; Austin and Houze Jr 1973; Sui et al. 1989). Included within the set of DL schemes is the zero-drag (ZD) approximation (Schneider and
Lindzen 1976; Shapiro and Stevens 1980; Sui et al. 1989),

\[ F = 0 \quad \text{(ZD)}, \]

which is a suitable approximation for sufficiently large updrafts (Newton and Newton 1959; Hitschfeld 1960).

The second approach, due to Gregory et al. (1997, hereafter, GKI) is to approximate the pressure force as proportional to the updraft velocity and the environmental shear,

\[ F = CM \partial_z v \quad \text{(GKI)}, \]

where \( C \) is a positive constant, \( M \) is the convective mass flux, and \( v \) is the environmental wind. This is the default scheme in version 5.1 of the Community Atmosphere Model (CAM, Neale et al. 2010). Note that this representation of the pressure force has no dependence on the cloud velocity \( v_c \). This can lead to some unusual consequences: if a cloud is both rising and moving relative to the air in the direction of shear, this force would accelerate the cloud rather than decelerate it.

The theoretical underpinnings for the GKI scheme are an analysis of linearized equations and a dominant-balance argument for the Poisson equation for pressure. In the analysis of linearized equations, the base state is an atmosphere with vertical shear, but no vertical motion (Rotunno and Klemp 1982; Wu and Yanai 1994). Since the linearized equations cannot represent convective momentum transport (which would be quadratic in the deviations), it is not clear how relevant this analysis is to CMT. In the dominant-balance argument, several terms are discarded (including those responsible for all of the form drag in 2D and most of the form drag in 3D) to arrive at an approximate Poisson equation,

\[ -\nabla^2 (p'/\rho) \approx 2 \partial_z \vec{u}_h \cdot \vec{\nabla}_h w, \]
where a subscript $h$ denotes horizontal vector components. It is then assumed that $\partial_z \vec{u}_h$ is equal to the vertical shear in the environment, as motivated by the linear analysis (page 323, LeMone et al. 1988). There is no consensus on the value of $C$, with Gregory et al. (1997) recommending $C = 0.7$, Zhang and Wu (2003) suggesting $C = 0.55$, and CAM using $C = 0.4$ (Neale et al. 2010). With in situ observations of the pressure field around storms (e.g., Ramond 1978; LeMone et al. 1988; Jorgensen et al. 1991), it is difficult to differentiate between competing theories in the absence of veering or backing winds. A compelling, albeit anecdotal, piece of evidence comes from Figure 11 of Rotunno and Klemp (1982), where the pressure gradient in a simulated storm aligns more with the environmental shear than with the relative motion between storm and environment.

What we will see in section 2 is that the zero-drag and GKI schemes are equivalent in the sense that the GKI scheme, with its tunable parameter $C$, predicts a CMT that is equal to $1 - C$ times that predicted by the ZD scheme, i.e.,

$$\partial_t v|_{\text{GKI}} = (1 - C)\partial_t v|_{\text{ZD}}.$$ 

Section 3 will introduce the concept of a “transilient matrix for momentum.” This matrix will be diagnosed from cloud-resolving simulations and will show that the GKI scheme underestimates the compensating subsidence of momentum by a factor of $1 - C$. Section 4 will demonstrate this same result from a high-resolution large-eddy simulation (LES). Finally, the results will be summarized in section 5.
2. Equivalence of ZD and GKI schemes

Let us approximate the atmosphere by two parts: cloud and environment. Using the standard bulk-plume model, we assume that vertical velocity and horizontal velocity are uncorrelated within each of those two classes. The continuity equations for cloud and environment are then

\[
\frac{\partial}{\partial t}(\sigma_c \rho) + \frac{\partial}{\partial z}(\sigma_c \rho w_c) = e - d
\]

and

\[
\frac{\partial}{\partial t}(\sigma_e \rho) + \frac{\partial}{\partial z}(\sigma_e \rho w_e) = d - e
\]

and the corresponding horizontal momentum equations are

\[
\frac{\partial}{\partial t}(\sigma_c \rho v_c) + \frac{\partial}{\partial z}(\sigma_c \rho v_c w_c) = e v_e - d v_c + F
\]

and

\[
\frac{\partial}{\partial t}(\sigma_e \rho v_e) + \frac{\partial}{\partial z}(\sigma_e \rho v_e w_e) = d v_c - e v_e - F.
\]

Here, \(\sigma_c(z)\) is the fractional area of cloud and \(\sigma_e = 1 - \sigma_c\) is the fractional area of environment. The entrainment and detrainment rates, which have units of kg m\(^{-3}\) s\(^{-1}\), are denoted by \(e\) and \(d\), respectively. The horizontal and vertical velocities are denoted by \(v\) and \(w\) with subscripts \(c\) and \(e\) to denote cloud and environment, and \(F\) is the horizontal force per volume between cloud and environment.

Assuming that clouds adjust much faster to a steady state than the environment does, we can drop the tendency terms in the cloud momentum equation and the two continuity equations. We also assume that \(\sigma_c \ll 1\), so we can approximate \(\sigma_e\) by 1. For notational simplicity, we will now drop the \(e\) and \(c\) subscripts from all variables except \(v_c\): from here on, \(\sigma\) and \(w\) are understood to be the cloud fractional area and cloud vertical velocity, and
is the environment’s horizontal wind speed. This simplifies the equations to

\[
\frac{\partial_z M}{\rho} = e - d \quad \text{(1)}
\]

\[
\frac{\partial_t v}{\partial_z} = \partial_z [M(v - v_c)] \quad \text{(2)}
\]

\[
\frac{\partial_z v_c}{\partial_z} = \varepsilon(v - v_c) + F/M, \quad \text{(3)}
\]

where \(M = \sigma \rho w\) is the convective mass flux and \(\varepsilon = e/M\) is the fractional entrainment rate.

Given the profiles of \(M\) and \(\varepsilon\), the key to evaluating the tendency of the environmental wind is to calculate \(v_c\) from equation (3).

The zero-drag scheme is described by equations (1–3) with \(F\) set to zero. We can integrate (3) with \(F = 0\) to give

\[
v_c(z) = v(z_0)e^{-\int_{z_0}^z dz' \varepsilon(z')} + \int_{z_0}^z dz' \varepsilon(z')v(z')e^{-\int_{z_0}^{z'} dz'' \varepsilon(z'')} , \quad \text{(4)}
\]

where we have assumed that \(v_c(z_0) = v(z_0)\). Using (1) and (4) in (2), and defining the fractional detrainment rate \(\delta = d/M\), we get

\[
\rho \frac{\partial_t v}{\partial z} = M(z) \left[ -\delta(z)v(z) + \partial_z v(z) \right. \\
\left. + \delta(z)v(z_0)e^{-\int_{z_0}^z dz' \varepsilon(z')} + \delta(z) \int_{z_0}^z dz' \varepsilon(z')v(z')e^{-\int_{z_0}^{z'} dz'' \varepsilon(z'')} \right] . \quad \text{(5)}
\]

Note that \(v_c\) has been eliminated. This equation gives the tendency of \(v(z)\) as a function of \(v(z')\) for all \(z' \in [z_0, z]\).

The Gregory-Kershaw-Inness scheme (Gregory et al. 1997) is described by equations (1–3) with \(F = CM\partial_z v\), where \(C\) is a constant. Integrating equation (3) with \(F = CM\partial_z v\) gives

\[
v_c(z) = Cv(z) + (1 - C)v(z_0)e^{-\int_{z_0}^z dz' \varepsilon(z')} + (1 - C) \int_{z_0}^z dz' \varepsilon(z')v(z')e^{-\int_{z_0}^{z'} dz'' \varepsilon(z'')} , \quad \text{(6)}
\]
where we have used the same boundary condition of $v_c(z_0) = v(z_0)$. Using (1) and (6) in (2), we get

\[
\rho \partial_t v(z) = (1 - C)M(z) \left[ -\delta(z)v(z) + \partial_z v(z) 
\right. \\
+ \delta(z) v(z_0) e^{-\int_{z_0}^z dz' \varepsilon(z')} + \delta(z) \int_{z_0}^z dz' \varepsilon(z') v(z') e^{-\int_{z_0}^{z'} dz'' \varepsilon(z'')} \right]. \quad (7)
\]

This is exactly the same as the ZD solution (5), except that the right-hand side is multiplied by $1 - C$. Therefore, for a given mass flux and entrainment rate, the wind tendency predicted by the GKI scheme is identical to $1 - C$ times the wind tendency predicted by the ZD scheme.

Since these two schemes differ by $1 - C$, we should be able to identify which is more accurate by comparing against cloud-resolving and large-eddy simulations. We can accomplish this by applying a horizontal force to a convecting atmosphere and then evaluating how convection redistributes that horizontal momentum. In particular, we will want to focus on the effect of compensating subsidence, which is represented by the $\partial_z v$ terms in (5) and (7).

There are several reasons for focusing on this term. For one, this term often plays a dominant role in convective momentum transport (Mapes and Wu 2001). Therefore, modeling this term correctly in a CMT scheme is of paramount importance. In addition, the effect of this term is relatively easy to measure and interpret: unlike the other terms in (5) and (7), which involve $\varepsilon$ and $\delta$, the subsidence term involves only $\partial_z v$ and $M$, both of which are easy to calculate in a numerical simulation. Although $\varepsilon$ and $\delta$ can be measured directly using the methods of Romps (2010) and Dawe and Austin (2011), it is not obvious how to relate these directly measured rates to the effective rates appropriate for a bulk-plume model such as equations (1–3): Romps (2010) and Dawe and Austin (2011) showed that the directly measured values can differ significantly from the effective rates for the bulk-plume equations.
Furthermore, the pressure force can alias onto $\varepsilon$ and $\delta$. For small $v - v_c$, a pressure force $F$ that is a function of $v - v_c$ can be Taylor expanded to give $F = \beta M (v - v_c)$, for some $\beta(z)$. In this case, equations (5) and (7) get modified by replacement of $\varepsilon$ and $\delta$ with $\varepsilon + \beta$ and $\delta + \beta$, respectively. Note that the subsidence term is the one term whose interpretation is not complicated by the pressure force. Therefore, when $v - v_c$ is small in the sense that $F$ can be linearized, a DL scheme generates the same compensating subsidence as the ZD scheme. In summary, we will focus on the subsidence term because it is of great dynamical significance, its coefficient is straightforward to measure, and it is straightforward to interpret.

From (5), we see that the $\partial_z v$ term in the ZD scheme (and general DL schemes with small $v - v_c$) causes the wind profile to sink at a speed of $M/\rho$. From (7), we see that the GKI scheme causes the wind profile to sink at a speed of $(1 - C)M/\rho$. Our goal, then, is to diagnose the actual speed of momentum subsidence in cloud-resolving simulations to compare against these two predictions. Naively, we might consider initializing a cloud-resolving simulation with some wind profile and then watching as the wind profile descends with time. Unfortunately, there are effects in addition to compensating subsidence – i.e., the other terms in (5) and (7) – that make the evolution of the wind profile more complicated than pure subsidence. To isolate the effect of the $\partial_z v$ term in cloud-resolving simulations, we will diagnose the transilient matrix for momentum.

3. Transilient matrix

Let us first define what we mean by a transilient matrix (TM) for momentum. The concept of a TM for mass was first introduced by Stull (1984) and it was shown by Romps
and Kuang (2011) how to diagnose this matrix for moist convection. In general, a transient matrix is the discretization of a transient function (TF), which provides a linear map from the horizontally averaged profile of some quantity to the tendency of that profile due to convection. For example, the TF for horizontal momentum $b(z, z')$ is implicitly defined by

$$
\rho \frac{\partial}{\partial t} v(z) \bigg|_{\text{due to convection}} = \int dz' b(z, z') v(z'),
$$

where $v$ is the horizontally averaged wind in a particular direction. Similarly, the TM for horizontal momentum $b_{ij}$ is implicitly defined by

$$
\rho_i \frac{\partial}{\partial t} v_i \bigg|_{\text{due to convection}} = \sum_j \Delta z_j b_{ij} v_j,
$$

where $i$ and $j$ index vertical levels.

Note that equations (5) and (7) can be written in terms of a transient function. For the ZD scheme, $b(z, z')$ is given by

$$
b(z, z') = -d(z)\delta_D(z' - z) - M(z)\partial_z \delta_D(z' - z)
$$

$$
+ d(z)e^{-\int_{z_0}^z dz'' \varepsilon(z'')} \delta_D(z' - z_0) + d(z)\varepsilon(z') e^{-\int_{z_0}^{z'} dz'' \varepsilon(z'')} \mathcal{H}(z' - z_0)\mathcal{H}(z - z'),
$$

where $\delta_D$ is the Dirac delta function and $\mathcal{H}$ is the Heaviside step function. For a given $z$, $b(z, z')$ is a sum of local distributions containing: $\delta_D(z' - z)$ that gathers information on $v$ only in the immediate vicinity of $z$ (first two terms); $\delta_D(z' - z_0)$ that deposits momentum from $z_0$ (third term); and a nonlocal distribution that samples $v$ at all $z' \in [z_0, z]$ (fourth term). The GKI scheme can be written in terms of a transient function that is identical to (8) except for an overall coefficient of $1 - C$. For DL schemes with small $v - v_c$, the transient function is given by (8) with the entrainment and detrainment rates modified by the addition of the linearized pressure-force coefficients. For a discrete vertical grid, $b(z, z')$ becomes a
matrix $b_{ij}$, whose indices range over the vertical levels. By generalizing the method of Romps and Kuang (2011), we can diagnose this matrix directly from cloud-resolving simulations.

In Romps and Kuang (2011), it was possible to diagnose the TM for mass in a single simulation by injecting a unique radioactive tracer into each of the $N$ vertical levels. Each tracer was advected passively with the flow with a steady source at its injection level and radioactive decay everywhere; the resulting distribution of tracers was used to infer $b_{ij}$. Note, however, that the TM for momentum is not, in general, the same as the TM for mass. This is because momentum can be transmitted between two parcels without exchanging any mass. Therefore, to diagnose a TM for momentum, it is not possible to use artificial tracers. Instead, we must use momentum as its own tracer. In this approach, horizontal momentum is uniformly injected into a vertical level (i.e., the air in that level is accelerated) and the horizontally averaged momentum is damped to zero with a timescale of 12 hours, which is long compared to the timescale for vertical transport in a cloud (see the discussion in Romps and Kuang 2011).

Since there are only two independent components of momentum ($x$ and $y$), we must run multiple simulations. In principle, $N/2$ simulations could be run, where $N$ is the number of vertical levels. For simplicity, however, $N$ simulations are run, each of which has $x$ momentum injected into a corresponding level. The cloud-resolving model used for these simulations is Das Atmosphärische Modell (DAM, Romps 2008). The simulations use the same doubly periodic domain ($32$ km $\times$ $32$ km $\times$ $30$ km), grid spacings ($2$ km horizontal, variable vertical), radiation (equator, January 1, no diurnal cycle), and lower boundary (300-K ocean) as used by Romps and Kuang (2011), which gives deep marine convection in radiative-convective equilibrium. To simplify the analysis of the momentum budget, the
lower boundary is specified to be free-slip. To avoid feedbacks on the surface fluxes, a bulk aerodynamic formula is used with a fixed wind speed of 5 m s$^{-1}$.

The transilient matrix is a linear operator, which implies that the quantity being transported by convection does not affect the convection itself. For horizontal momentum, this is not necessarily the case: a sufficiently large shear can blow apart convecting clouds, altering the convective mass fluxes. Therefore, we wish to use an applied force that is small enough to ensure the passivity of momentum transport. On the other hand, we also want a good signal-to-noise ratio in the resulting wind profile, which is obtained with a stronger applied force. This tradeoff is explored using nine different sets of simulations, each with a different magnitude of forcing applied to a single vertical level. The applied forcing ranges from $3.125 \times 10^{-5}$ m s$^{-2}$ to $8 \times 10^{-3}$ m s$^{-2}$ by factors of two. Since there are 64 vertical levels in the cloud-resolving simulation, this requires $64 \times 9 = 576$ cloud-resolving simulations, each of which is run for 60 days with the first two days discarded as spinup. Figure 1 shows the peak value of the steady-state wind profile $v$ normalized by the applied forcing $A$, plotted as a function of applied forcing. There are 64 curves, each corresponding to the forcing being applied to a particular level. If the response were linear, as desired, then the curves would all be flat at a normalized value of one. Up to an applied forcing of about $5 \times 10^{-4}$ m s$^{-2}$, the response remains linear for most levels, so this is the acceleration used in the calculation of the transilient matrix. The three levels with the largest deviations from linearity are the lowest three layers, which suggests that the transilient matrix may not be as reliable in the vicinity of the surface.

Now, let $S(z)$ be a constant external source of horizontal momentum and let $\tau$ be the timescale over which momentum is damped to zero. Then, the mean wind profile $v(z,t)$
evolves as
\[
\partial_t \left[ \rho(z) v(z, t) \right] = S(z) - \rho(z) v(z, t)/\tau + \int dz' b(z, z') v(z', t),
\]
where the three terms on the right-hand side correspond to the external forcing, Rayleigh
damping, and convective momentum transport. Following Romps and Kuang (2011), we
can discretize this equation into \( N \) height levels (corresponding to the \( N \) levels of the cloud-
resolving simulation). By diagnosing the wind profile from \( N \) different simulations (each
with a different and linearly independent profile \( S \)), we can assemble the \( N \) equations for \( v \)
into a matrix equation that can be solved for \( b \). Analogous to equation (9) in Romps and
Kuang (2011), the transient matrix for momentum is diagnosed as

\[
b_{ij} = \frac{1}{\Delta z_j} \sum_k \left[ \partial_t (\rho_i v_{ik}) + \frac{\rho_i v_{ik}}{\tau} - S_{ik} \right] (v^{-1})_{kj},
\]

where \( v_{ik} \) is the horizontally averaged \( x \) velocity at height \( i \) in simulation \( k \), \( S_{ik} \) is the applied
acceleration at height \( i \) in simulation \( k \) (\( S_{ik} = a \delta_{ik} \), where \( a/\rho_i = 5 \times 10^{-4} \) m s\(^{-2}\)), \( \rho_i \) is the
air density at height \( i \), \( \Delta z_j \) is the vertical grid spacing at height \( j \) (ranging from 50 m near
the surface, to 500 m in the mid troposphere, to 1000 m in the stratosphere), and \( \tau \) is
the damping time of 12 hours. Each simulation was run for two months with the \( v_{ik} \) and
\( \partial_t v_{ik} \) averaged over all but the first two days, which were discarded as spinup. Putting the
resulting \( v_{ik} \) and \( \partial_t v_{ik} \) into (9) gives the result shown in Figure 2. The left panel displays the
matrix in units of kg m\(^{-4}\) s\(^{-1}\). Hewing to convention, the matrix is displayed upside down
so that the destination height (on the \( y \) axis) increases upwards. The right panel plots a
sample row of the matrix.

As we see from Figure 2, the most prominent matrix elements are in the vicinity of
the diagonal. These elements constitute the local operators, which are larger than other
elements of the matrix because they contain factors of $1/\Delta z$. For example, $\int dz' b(z, z') f(z')$ acts as the unit operator on $f$ when the transilient function $b(z, z')$ is a delta function, which corresponds to a transilient matrix with $1/\Delta z$ on the diagonal. Other local operators – such as $\partial_z$ and $\partial_z^2$ – are represented in $b_{ij}$ by the finite-difference approximations to those derivatives. The order of accuracy of these stencils will depend on the highest-order local operator that is contained in the matrix. Table 1 gives examples of the mappings between operators, transilient functions, and transilient matrices for the case of a constant vertical grid spacing and with local operators confined to a three-point stencil (i.e., in which the highest-order operator is $\partial_z^2$).

It is clear from the second panel of Figure 2 that the local operators occupy a five-point stencil. For each row of $b_{ij}$, the five elements $\{b_{i,i-2}, \ldots, b_{i,i+2}\}$ form a stencil that can be decomposed into operators proportional to $1$, $\partial_z$, $\partial_z^2$, $\partial_z^3$, and $\partial_z^4$ (see Appendix A). We write the coefficients of these operators as $c_0$ through $c_4$. These coefficients will, in general, be a function of height. For our purposes, we are interested in $c_1(z)$, because this is the coefficient of $\partial_z$, the operator corresponding to subsidence. The drag-law scheme predicts that the wind profile subsides at a speed of $c_1/\rho = M/\rho$ and the Gregory-Kershaw-Inness scheme predicts $c_1/\rho = (1 - C)M/\rho$.

Figure 3 plots the value of $c_1/\rho$ diagnosed from the transilient matrix (solid line). This is the speed at which momentum subsides in the cloud-resolving simulations. The dashed line plots the speed $M/\rho$ at which mass subsides, which is also the DL prediction for the speed of momentum subsidence. Here, the convective mass flux $M$ is diagnosed as the horizontally and temporally averaged value of $\mathcal{A}_w$, where $\mathcal{A}$ is unity where $w \geq 1$ m s$^{-1}$ and the condensed-water mixing ratio $q_c$ satisfies $q_c \geq 10^{-5}$ kg kg$^{-1}$, and is zero elsewhere.
Overall, we see that the DL prediction is an excellent match with the diagnosed subsidence. The main differences are found in and above the tropical tropopause layer (TTL) and in the subcloud layer. In the TTL and above, the transient matrix reports a small downward subsidence of momentum, presumably due to the action of gravity waves. Below the cloud base, which is located at 500 meters, the DL prediction is zero because there is no cloud mass flux. Dry eddies are likely responsible for the momentum subsidence seen there. In the cloud layer, we can conclude that momentum subsides at the same speed as mass. The GKI prediction for the speed of momentum subsidence (dotted line) is too small by a factor of $1 - C$.

4. Large-eddy simulation

We can also confirm this result in a large-eddy simulation. Unfortunately, LES is too computationally expensive to allow for constructing a transient matrix, which requires as many simulations as there are vertical levels. Instead, we can examine the response to an applied forcing in a single simulation and compare the resulting winds to the predictions from the CMT schemes.

The LES used here has a horizontal grid spacing of 200 m and a vertical spacing of 50 meters between 3 km and 15 km. The doubly periodic horizontal domain is 38.4 km by 38.4 km, and the model top is at 30 km. An acceleration of $a = 5 \times 10^{-4} \text{ m s}^{-2}$ (the same as in the previous section) is applied on a single grid level at 6 km, which corresponds to an applied external force of $A = a \rho \Delta z = 0.016 \text{ N m}^{-2}$. As in the previous section, the horizontally averaged momentum is damped to zero on a timescale of $\tau = 12$ hours. The simulation is
run to equilibrium for over a week, and statistics are collected over the last three days.

Qualitatively, what sort of steady-state wind profile should we expect from this simulation? Applying an external force $A \, (\text{N m}^{-2})$ at injection height $z_i$, damping the wind to zero over a timescale $\tau$, and assuming a steady state, equations (2) and (3) become

\[ 0 = \partial_z [M(v - v_c)] + A\delta_D - \rho v / \tau \quad (10) \]
\[ \partial_z v_c = \varepsilon(v - v_c) + F / M, \quad (11) \]

where $\delta_D = \delta_D(z - z_i)$ is the Dirac delta function centered on $z_i$. For the moment, let us assume that $F = 0$. As shown in appendix B, the full analytical solution to these equations for zero $F$ and constant $M$, $\varepsilon$, and $\rho$ is

\[ v = \frac{\varepsilon + \lambda_{\text{sign}(z_i - z)} A}{\lambda_+ - \lambda_-} \frac{A}{M} \exp \left[ \lambda_{\text{sign}(z_i - z)}(z - z_i) \right], \quad (12) \]
\[ v_c = \frac{\varepsilon}{\lambda_+ - \lambda_-} \frac{A}{M} \exp \left[ \lambda_{\text{sign}(z_i - z)}(z - z_i) \right], \quad (13) \]

where

\[ \lambda_\pm = \frac{\rho}{2M\tau} \left( 1 \pm \sqrt{1 + 4M\varepsilon\tau / \rho} \right). \quad (14) \]

Equation (12) for $v$ takes the form of two exponentials stitched together discontinuously at $z_i$. Equation (13) for $v_c$ takes the form of two exponentials stitched together continuously at $z_i$.

In this solution, the ratio of the windspeed $v$ just above $z_i$ to the windspeed just below $z_i$ is equal to

\[ \frac{2x + 1 - \sqrt{1 + 4x}}{2x + 1 + \sqrt{1 + 4x}}, \quad (15) \]

where $x = M\tau\varepsilon / \rho$. This ratio is plotted in Figure 4. For tropical RCE, typical mid-tropospheric values are $M = 0.01 \, \text{kg m}^{-2} \, \text{s}^{-1}$, $\rho = 0.5 \, \text{kg m}^{-3}$, and $\varepsilon \lesssim 1 \, \text{km}^{-1}$. For $\tau = 12$
hours as used here, $M \varepsilon / \rho \lesssim 1$. According to Figure 4, this means that the windspeed just above $z_i$ is $\lesssim 10\%$ the windspeed just below $z_i$. Therefore, we can approximate the solution for $v$ to within an error of 10\% by setting $\varepsilon$ to zero. This gives

$$v = \frac{A}{M} \exp \left[ \frac{\rho}{M \tau} (z - z_i) \right] \mathcal{H}(z_i - z), \quad (16)$$
$$v_c = 0, \quad (17)$$

where $\mathcal{H}$ is the Heaviside step function. In this approximation, convection acts only to advect the wind profile downward with the speed $M/\rho$.

A similar conclusion applies to the case where the pressure force on the cloud is described by some function $F(v - v_c)$. For sufficiently small $v - v_c$, we can Taylor expand $F$. Noting that $F(0) = 0$ by symmetry, the Taylor expansion to first order gives $F = F'(0) (v - v_c)$. Adding this pressure force simply modifies (12) and (13) by replacement of $\varepsilon$ with $\varepsilon + F'(0)/M$. Therefore, (16) is a good approximation so long as $[M \varepsilon + F''(0)] \tau / \rho \ll 1$. Figure 5 shows the full analytical solution (12,13) and the simplified analytical solution (16,17) for the values of $M$, $\rho$, and $\varepsilon$ diagnosed at 6 km in the LES. For the full analytical solution, the value of $\varepsilon$ is calculated using the direct measurement technique of Romps (2010). As expected, the full and simplified analytical expressions for $v$ are in close agreement. This is the shape of the wind profile $v$ that we should expect to see in both the LES and a faithful CMT scheme.

The average wind profile $v$ from the LES is shown in Figure 6 as the solid line. As in Figure 5, the simplified analytical expression is plotted as the dashed line. We see that the simplified analytical expression does an excellent job of predicting the shape of the LES wind profile $v$. Since the shape and magnitude of the analytical profile is set by the subsidence rate $M$, this confirms that momentum subsides at a speed equal to $M/\rho$. In addition, the
similarity between the LES $v$ in Figure 6 and the full-analytic $v$ in Figure 5 is striking.

On the other hand, the simplified $v$ profile predicted by the GKI scheme is given by equation (16) with $M$ replaced by $(1 - C)M$. This prediction is shown in Figure 6 as a dotted line. This confirms the conclusion from section 3: parameterizing the pressure-gradient force as $F = CM\partial_z v$, as in the GKI scheme, causes the wind profile to subside too slowly by a factor of $1 - C$.

5. Summary and discussion

We have seen that the Gregory-Kershaw-Inness (GKI) scheme for convective momentum transport (Gregory et al. 1997), which is the default in CAM 5.1, is exactly proportional to the zero-drag (ZD) scheme, which has no parameterization of the pressure force. That constant of proportionality is $1 - C$, where $C$ is specified to be 0.7 by Gregory et al. (1997) and Richter and Rasch (2008), and 0.55 by Zhang and Wu (2003). In the latest version of CAM 5.1, $C$ is set to 0.4. The findings presented here suggests that $C$ should be set all the way to zero, which would make the GKI scheme identical to the ZD scheme. This fits well with the results of Richter and Rasch (2008), who found that the ZD scheme (which they refer to as SL76) produced a more realistic climate than the GKI scheme (which they refer to as GKI97). Setting $C$ to zero also eliminates a potential numerical instability in the GKI scheme (Kershaw et al. 2000).

The numerical simulations were performed on the Lawrencium cluster provided by the IT Division at the Lawrence Berkeley National Laboratory and the Hopper cluster provided by the National Energy Research Scientific Computing Center, both of which are supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231. Thanks are due to Nadir Jeevanjee, Kyongmin Yeo, and three reviewers for their helpful feedback on the manuscript.

APPENDIX

A. Operator decomposition

Given the discretization \( \{ q_i = q(z_i) : i = 1, \ldots, N \} \) of some profile \( q(z) \), the derivatives up to fourth order of \( q(z) \) at \( z_i \) can be approximated by

\[
\begin{pmatrix}
q(z_i) \\
\partial_z q(z_i) \\
\vdots \\
\partial_z^4 q(z_i)
\end{pmatrix}
\approx
S
\begin{pmatrix}
q_{i-2} \\
q_{i-1} \\
\vdots \\
q_{i+2}
\end{pmatrix},
\]

18
where \( S \) is a stencil matrix. Since \( S \) is a non-degenerate matrix, there exist coefficients \( c_{ip} = c_p(z_i) \) such that

\[
\int dz \, b(z_i, z) \, q(z) \approx \sum_j \Delta z_j \, b_{ij} \, q_j = \sum_{p=1}^{5} \Delta z_{i+p-3} \, b_{i,i+p-3} \, q_{i+p-3} + \text{NLT}
\]

\[
= \sum_{r,p=1}^{5} c_{r-1}(z_i) \, \partial^{-1}_r q(z_i) + \text{NLT},
\]

where

\[
\text{NLT} = \sum_{j \notin [i-2,i+2]} \Delta z_j \, b_{ij} \, q_j
\]

are the non-local terms. We see that the near-diagonal elements of \( b \) can be expressed in terms of the coefficients \( (c_0, c_1, \ldots, c_4) \) of local operators \( (1, \partial_z, \ldots, \partial_z^4) \), where the coefficient \( c_p \) has units of \( \text{kg m}^{p-3} \text{s}^{-1} \). These coefficients are related to the transilient matrix via

\[
c_{r-1}(z_i) = \sum_{p=1}^{5} b_{i,i+p-3} \, \Delta z_{i+p-3} \, T_{pr},
\]

where \( T \equiv S^{-1} \) is the matrix of Taylor-series coefficients.

**B. Analytical wind profile**

Consider equations (10) and (11) with \( M, \varepsilon, \rho, \) and \( \tau \) that are constant with height and \( F = 0 \). Assuming that \( v_c(z_0) = v(z_0) \) for some \( z_0 \), we can integrate (11) to give

\[
v_c(z) = \varepsilon e^{-\varepsilon z} \int_{z_0}^{z} dz' e^{\varepsilon z'} v(z') + e^{-\varepsilon(z-z_0)} v(z_0). \tag{A1}
\]

Plugging this into equation (10) gives

\[
M \partial_z v(z) + M \varepsilon^2 e^{-\varepsilon z} \int_{z_0}^{z} dz' e^{\varepsilon z'} v(z') - M \varepsilon v(z)
\]

\[
+ M \varepsilon e^{-\varepsilon(z-z_0)} v(z_0) - \rho(z)v(z)/\tau + A \delta_D = 0. \tag{A2}
\]
When $A = 0$, we can look for solutions of the form $v = e^{\lambda z}$. For $v(z_0) = 0$ and $z$ far from $z_0$ in the sense that $(z - z_0)\rho/M\tau \gg 1$, $v = e^{\lambda_+ z}$ and $v = e^{\lambda_- z}$ are solutions when $A = 0$ and

$$\lambda_{\pm} = \frac{\rho}{2M\tau} \left( 1 \pm \sqrt{1 + 4M\varepsilon\tau/\rho} \right).$$

For $A \neq 0$, the solution can be found by stitching together these two exponential solutions to either side of $z_i$. To satisfy the requirement that $v = 0$ at $z = \pm\infty$, we need to use $\lambda_+$ for $z < z_i$ and $\lambda_-$ for $z > z_i$. Let us denote the amplitude of $v$ just below and above $z_i$ by $C_1$ and $C_2$, respectively. Integrating (A2) over an infinitesimal height interval centered on $z_i$ reveals that $C_1 = C_2 + A/M$. When we integrate (A2) over all heights (again, neglecting terms involving an exponential of $z_0$), we find that the sum of the first four terms integrate to zero identically. This is a consequence of the fact that those terms represent the rearrangement of momentum in the vertical: they cannot generate a net source or sink of momentum.

Therefore, the integral of (A2) over all $z$ reduces to

$$0 = \int_{z_0}^{\infty} dz \left( -\frac{\rho v}{\tau} + A\delta_D \right) = A - \frac{\rho}{\tau} \left( \frac{C_1}{\lambda_+} - \frac{C_2}{\lambda_-} \right).$$

Using $C_1 = C_2 + A/M$ reveals the solution given in equation (12). Substituting this expression into (A1) gives equation (13).
