Photoproduction is studied at 2.8 and 4.7 GeV using a linearly polarized monoenergetic photon beam in a hydrogen bubble chamber. We discuss the experimental procedure, the determination of channel cross sections, and the analysis of the channel $\gamma p \rightarrow p\pi^+\pi^-$. A model independent analysis of the $\rho^0$ decay angular distribution allows us to measure nine independent density matrix elements. From these we find that the reaction $\gamma p \rightarrow pp^0$ proceeds almost completely through natural parity exchange for momentum transfers $|t| < 1 \text{ GeV}^2$ and that the rho production mechanism is consistent with s-channel c.m.s. helicity conservation for $|t| < 0.4 \text{ GeV}^2$. A cross section for the production of $\pi^+\pi^-$ pairs in the s-channel c.m.s. helicity-conserving p-wave state is determined. The rho mass shape is studied as a function of momentum transfer and is found to be inconsistent with a t-independent Ross-Stodolsky factor. Using a t-dependent parameterization of the $\rho^0$ mass shape we derive a phenomenological $\rho^0$ cross section. We compare our phenomenological $\rho^0$ cross section with other experiments and find good agreement for $0.05 < |t| < 1 \text{ GeV}^2$. We discuss the discrepancies in the various determinations of the forward differential cross section. We study models for $\rho^0$ photoproduction and find that the Söding model best describes the data. Using the Söding model we determine a $\rho^0$ cross section. We determine cross sections and nine density matrix elements for $\gamma p \rightarrow \Delta^{++}\pi^-$. The parity asymmetry for $\Delta^{++}$ production is incompatible with simple one pion exchange. We compare $\Delta^{++}$ production with models.

I. Introduction

This is the first of two final reports on an experiment which used the 82" LRL-SLAC hydrogen bubble chamber to study photoproduction of hadrons by a polarized photon beam at 2.8 and 4.7 GeV. This beam yields photons of more than 90% linear polarization at our energies, with an energy resolution of $\pm (3-4)\%$ between 3 and 5 GeV. We have obtained 92 $< 150 >$ events/µb at 2.8 $< 4.7 >$ GeV. In this paper we present the general analysis procedure, total and partial hadronic cross sections for the various topological channels, and a detailed study of the three-body reaction $\gamma p \rightarrow p \pi^+ \pi^-$ with particular emphasis on $\rho^0$ and $\Delta^{++}$ production. We have already published a measurement of the total hadronic photoproduction cross section$^1$, and preliminary results on $\rho^0 2, 3, 4, 5$ production and $\rho^0 - \omega$ interference$^6$. These will be treated in this and a forthcoming paper in greater detail and subjected to further analysis.

This experiment, which uses the SLAC Compton backscattered laser beam$^7, 8, 9$, has the following advantages, not all of which are found in previous studies of multibody photoproduction: a monoenergetic photon spectrum, a $4\pi$ detection efficiency, and a polarized beam. By exploiting the narrow energy spectrum and the $4\pi$ detection geometry of the bubble chamber we measure the total hadronic photoproduction cross section to an accuracy of $\pm 2.4\%$. We also determine channel cross sections for reactions with 3, 5 or 7 charged outgoing particles, for those with one additional neutral particle, and the sum of the cross sections for channels with more than one neutral particle.

Photoproduction of $\rho^0$ mesons in the reaction $\gamma p \rightarrow p \pi^+ \pi^-$ is known$^{10-12}$ to be mainly a diffractive process. The evidence for this came from the
magnitude and the energy dependence of the production cross section above 2 GeV. In addition, there have been indications that the photoproduced $\rho^0$ mesons are transversely aligned in the helicity system. Knowing the polarization of the photons and using the 4π geometry of the chamber we are able to make a detailed analysis of the $\rho^0$ production mechanism. The use of polarized photons adds six new independent density matrix parameters to the three derivable from unpolarized photons. As a direct result, we can separate the cross sections for $\rho^0$ production into contributions from natural ($P = (-1)^J$) and unnatural ($P = (-1)^{J+1}$) parity exchanges in the $t$-channel. We find that $\rho^0$ photoproduction is dominated by natural parity exchange for momentum transfers squared from target to proton, $|t|$, less than 1 GeV$^2$, as expected for a diffractive process. We confirm the transverse alignment of the $\rho^0$'s in the helicity system for $|t| < 0.4$ GeV$^2$ and find that the data are consistent with $s$-channel helicity conservation in $\rho^0$ photoproduction.

We further determine the cross section for $s$-channel helicity-conserving $p$-wave dipion states which dominate the $\rho^0$ region. We emphasize that the above results are model-independent.

One of the puzzles of $\rho^0$ photoproduction has been the apparent skewing of the $\rho^0$ mass shape. We confirm the skewing and show that it depends on $t$. Using an empirical formula which describes this $t$-dependence we determine a phenomenological cross section for $\rho^0$ production.

We also compare the observed features of dipion production in the $\rho^0$ region with several theoretical models and find that a modified Söding model is best able to reproduce quantitatively the mass-shift, its $t$-dependence, and the decay properties of the dipion system. We also obtain $\rho^0$ cross sections using the Söding model.
Since there have been substantial discrepancies among the published forward differential cross sections for $\rho^0$ photoproduction we compare these cross sections and discuss the differences; we show that there are theoretical as well as experimental problems.

We have determined cross sections for $\Delta^{++}$ production in the process $\gamma p \rightarrow p\pi^+\pi^-$. Using an analysis similar to that used for $\rho^0$ production we show that $\Delta^{++}$ production proceeds through a mixture of natural and unnatural parity exchanges in the t-channel.

II. Experimental Procedure

A. Beam

In 1962, R. Milburn,\textsuperscript{13} concurrently with F. Arutyunian, et al.,\textsuperscript{14} pointed out that backward Compton scattering of an intense polarized laser light beam by high energy electrons would produce useful yields of nearly monoenergetic, polarized photons. Such a beam was used for this experiment.\textsuperscript{7,8,9}

Because the reaction

$$\gamma(k_f) + e^- (E_e) \rightarrow e^- + \gamma(k_f)$$

is a two-body process, for a fixed incident geometry the energy $k_f$ of the scattered photon depends only on its laboratory angle, $\theta$, as measured with respect to the incident electron beam. For a head-on collision and small $\theta$ it can be shown that when the energies of the incoming photon, $k_i$, and electron $E_e$ are fixed:

$$k_f \approx \frac{k_{f \text{max}}}{1 + \frac{E_e^2 \theta^2}{s}}$$  \hspace{1cm} (1)
where \( s \) is the center of mass energy squared,

\[
s \approx m_e^2 + 4k \cdot E_e,
\]

\[
k_f^\text{max} \approx \frac{4E_e^2k_i}{s}.
\]

By collimating the backscattered photon beam and incident electron beam we select a band of photon energies given by

\[
\frac{k_f^\text{max} - k_f^\text{min}}{k_f^\text{max}} \approx \frac{k_f^\text{max}}{4k_i} \frac{\theta_c^2}{c},
\]

where \( \theta_c \) is the collimator half-angle (\( \approx 10^{-5} \) radians). For this experiment, \( k_i = 1.78 \text{ eV} \). Thus, the energy resolution (FWHM) is expected to vary from about 2% for \( k_f^\text{max} = 1.44 \text{ GeV} \) (\( E_e = 8 \text{ GeV} \)) to 6.5% for \( k_f^\text{max} = 4.7 \text{ GeV} \) (\( E_e = 16 \text{ GeV} \)). Another feature of the Compton process is that if the incident light is polarized, after backscattering (\( \theta \approx 0^\circ \)), it is still almost completely polarized in the same way. (Formula 4 of Ref. 7)

Figure 1 shows the beam layout. About \( 3 \times 10^{11} \) electrons in a 1.5 \( \mu \) sec pulse passed through the five-meter-long interaction region. The electron beam in the interaction region was 1 cm in diameter with a divergence of about \( 10^{-5} \) radians (actual beam phase space = \( (10^{-6} \text{ rad-cm})^2 \)). The incident linearly polarized light beam was obtained from a Q-switched ruby laser of wave length 0.6943 \( \mu \) (\( k_i = 1.78 \text{ eV} \)) with a maximum output of two joules emitted into a phase space of about \( (0.75 \text{ mrad-cm})^2 \). The pulse duration was about 50 nsec. The plane of linearly polarized light could be rotated 90° by inserting a half-wave plate into the laser beam line. After the electron and
laser beams clashed at a relative angle of 3 milliradians, the electron beam was deflected into a dump. To minimize the synchrotron radiation the electron beam first traversed a weak magnetic field until it was clear of the beam line. The synchrotron radiation resulting from electrons deflected in this weak field had low enough energy to be removed by a high-Z photoelectric absorber (0.16 radiation lengths of uranium) which did not produce any significant deterioration of the high-energy photon spectrum at the bubble chamber. The Compton backscattered photon beam was collimated to $\approx 10^{-5}$ radians by a collimator with a 2 mm diameter hole located 100 meters downstream of the interaction region. Four quadrant scintillators surrounded the hole behind one inch of Hevimet. The showers in these scintillators allowed us to determine the beam steering to about $10^{-6}$ radians and to monitor the beam intensity. Our electronics vetoed picture taking if the beam was mis-steered more than $3 \times 10^{-6}$ radians or if the intensity was too high or too low. Control of the intensity was accomplished by adjusting the laser output or the electron beam intensity. (For more details see Sec. III of Ref. 15)

B. Photon Energy Spectrum and Polarization

The energy of the scattered photon depends on the energies of the initial photon and the electron beam. For the ruby laser used, electron energies of 12 and 16 GeV gave mean photon energies of 2.8 and 4.7 GeV, respectively, for the two exposures discussed in this paper. The energy spectra are shown in Fig. 2; the method by which they were obtained is discussed in Section III-A.

The polarization of the incident laser light, which was assumed to be 100%, was measured in the interaction region to be greater than 97%. A half-wave plate was used in 50% of the pictures to rotate the polarization
direction by $90^\circ$. The degree of linear polarization of the backscattered photon beam was calculated using the formalism of Ref. 7 by averaging over the experimental energy spectrum between the energy limits given in Table I and Fig. 2. The average polarization was $95\% < 93\% > 2.8 < 4.7 > \text{GeV}$. The particular half-wave plate used in 18% of the exposure, when combined with the rest of the run, reduced these values by $2 \pm 1\%$. We estimate the overall uncertainty in the polarization to be $\pm 2\%$.

The alignment and transport of the laser beam introduces an uncertainty in the polarization direction of the high energy photons at the bubble chamber. Although the polarization direction was measured to an accuracy of one degree at the laser, we estimate the total uncertainty from all effects to be $\pm 3^\circ$ at the bubble chamber for the polarization state without the half-wave plate. For the half-wave plate data we estimate a further uncertainty of $\pm 5^\circ$ in polarization direction. These uncertainties introduce a systematic uncertainty in quantities such as the parity asymmetry $P_\sigma$ (see Sec. IV-B 3) and the total helicity-conserving p-wave $\pi\pi$ intensity $II$ (see Sec. IV-B 6). For the combined data these uncertainties are less than 2%.

The average polarization and a summary of the beam and exposure are given in Table I.

C. Bubble Chamber

Approximately 750,000 pictures were taken in the Lawrence Radiation Laboratory (LRL) - SLAC 82-inch hydrogen bubble chamber. The magnetic field at the center of the chamber was 16.6 kG. Most of the pictures were taken with $\sim 50$ photons per pulse corresponding to about seven $e^+e^-$ pairs per picture and about one hadronic event every twenty-five frames.
D. Scanning Procedures

Both events and pairs were scanned for within a fiducial area of ± 4 mm width in the bubble chamber along the beam line (the beam has a diameter of 3 mm). The length of the scanning area was chosen to allow a minimum track length of 35 cm for forward going tracks and 8 cm for backward tracks.

Hadronic events could be easily separated from the pair background since hadronic tracks generally have much larger production angles than the $e^+e^-$ tracks, which are produced close to $0^\circ$.

The film was double-scanned with discrepancies resolved in a third pass. The combined double-scan efficiency was found to be $\geq 99\%$ for all events except one-prongs, strange particle decays and three-prongs with short recoil protons. The biases in the $p^+\pi^-$ channel will be discussed in Sec. III-A. Pairs were counted in both scans on four frames per roll of 660 frames. Discrepancies between the two scans in counting pairs were resolved in a third scan. We estimate uncertainties in the number of pairs counted (as compared to the number of events) to be $(0 \pm 2)\%$.

Equal numbers of pictures were taken with the polarization horizontal and vertical in the bubble chamber in order to check for biases. No detectable differences were found between the two polarizations. Both laboratories scanned a common subset of the film (25%). Comparison of these scan results for the different laboratories was used to obtain scanning efficiencies.

The numbers of events found in the scan are shown in Table II.

E. Measuring and Kinematical Reconstruction

Half the events were measured at SLAC and half at LRL. SLAC used conventional measuring machines throughout, while the last two-thirds of the
first measurements at LRL were processed by Spiral Reader II: the passing rate and resolution were comparable to conventional measuring machines. When remeasurements were stopped, \( \approx 2\% \) of events remained to be re-measured. The fraction of events that could not be measured due to secondary scatters or track obscuration was \( \approx 5\% \) (see Table II).

At both laboratories the events were analyzed using the geometrical reconstruction program TVGP and the kinematics program SQUAW.\(^{16}\) The hypotheses attempted in SQUAW are given in Table II. No constraint was placed on the incident gamma energy; the beam direction, as determined from measurements of \( e^+e^- \) pairs, was assigned errors of \( \approx \pm 1 \text{ mrad} \) in dip and azimuth. Hence, hypotheses 1, 4 and 5 have 3-constraints in the kinematical fit and 2 and 3 have no constraints. Fits were accepted if they were compatible with the observed bubble density. Three-constraint fits were required to have kinematic \( \chi^2 < 30 \) (see also theses of K. C. Moffeit\(^ {17}\) and W. J. Podolsky\(^ {15}\)); competing \( O-C \) fits were ignored.

The bubble chamber magnetic field and the reconstruction procedure were checked by measuring \( K^0 \) decays; as shown in Fig. 3, the \( K^0 \) mass is correct to \( 0.2\% \). The \( \pi^+\pi^- \) mass resolution at the \( K^0 \) mass is \( \pm 5 \) MeV. The combined data for the two energies are given in Fig. 3; we find no significant differences between the two samples.

In order to compare the measurement and analysis procedures at LRL and SLAC, the 2.8 GeV three pronged events measured at SLAC were remeasured on Spiral Reader II and processed through the LRL analysis system. A comparison of the two sets of measurements showed that fitted angles and momenta, and such quantities as invariant masses and decay angles, agreed within one standard deviation and that kinematic interpretations agreed for \( > 99\% \) of the events.\(^ {15, 17}\)
III. Cross Sections

A. Procedures

Using the number of $e^+e^-$ pairs together with the known pair production cross section on hydrogen ($\sigma_{\text{pair}}$) we obtain hadronic cross sections from

$$\sigma(\gamma p \rightarrow \text{hadrons}) = \left(\frac{N_{\text{events}}}{N_{\text{pair}}}\right)\sigma_{\text{pair}}$$

The pair cross sections used in this paper are given in Table III. They result from a calculation by Knasel\textsuperscript{18} and are 1% higher than the values used in our earlier publications.\textsuperscript{1-6} The new values of Knasel are claimed to be accurate to $\pm 0.5\%$ and have been verified to $\pm 1\%$.\textsuperscript{19}

To exclude events and pairs produced by non-beam photons originating in the bubble chamber window or hydrogen, the vertices of events and pairs used for the final analysis are required to be within a fiducial volume. This fiducial volume is defined by a cylinder along the beam direction $y$ given by

$$R = \sqrt{(x-x_0(y))^2 + \left(\frac{z-z_0(y)}{2}\right)^2} < 2 \text{ mm}$$

where $x_0(y)$ and $z_0(y)$ were obtained from a straight line fit to the vertex position of the events and $(x,y,z)$ is the vertex position of the individual event or pair. Note that this expression takes account of the larger errors in the measurement of depth in the bubble chamber ($z$ direction). The fraction of hadronic events outside the fiducial volume was determined directly from the measured vertex distributions. The fraction of photons, and hence of pairs, with $E_\gamma > 0.5$ GeV outside the fiducial volume was calculated from
the vertex distribution of events fitting $\gamma p \rightarrow p\pi^+\pi^-$ using the known pair and event cross sections. For pairs with $E_\gamma < 0.5$ GeV the correction was found from the vertex distribution of measured pairs. These corrections were applied to the numbers of pairs and hadronic events found in scanning (Table II). Their values are given in Table IV. For more details see Refs. 15 and 17.

The photon energy spectrum, for $E_\gamma > 0.5$ GeV, was found from the $E_\gamma$ distribution of events, within the fiducial volume, which fit $\gamma p \rightarrow p\pi^+\pi^-$ (3C fit). We used the known cross sections for this channel $^{11}$ and assumed that the cross section was constant within the energy region $2.4 - 3.3 < 4.1 - 5.3 >$ GeV for the $2.8 < 4.7 >$ GeV exposure. This procedure is more accurate than one using $e^+e^-$ pairs since bremsstrahlung gives rise to large electron energy losses (c.f. Fig. 1 of Ref. 1). The error in the photon energy determination from the 3C fit to $\gamma p \rightarrow p\pi^+\pi^-$ is small ($\sim 1\%$) and so has a negligible broadening effect on the spectra. For $E_\gamma < 0.5$ GeV the measured pair energy spectrum was used after dividing out the energy dependence of the pair cross section. The spectrum was normalized to that obtained from the 3C fits in the interval $0.5 < E_\gamma < 1.5$ GeV. The photon spectra obtained are shown in Fig. 2. The numbers of events and pairs produced by photons outside the energy limits given in Table I were calculated from the photon spectra of Fig. 2 and the known event and pair cross sections. These corrections are given in Table IV.

Both wide angle pair production (WAP), simulating hadronic events, and a reduced scanning efficiency necessitate corrections to the channel $\gamma p \rightarrow p\pi^+\pi^-$ for $|t| < 0.02 < 0.1 \gev^2$ for $2.8 < 4.7 \gev$. For $|t| > 0.02 \gev^2$ the corrections were determined from the scan efficiency $^{20}$
and by calculating the (small) WAP contamination. The combined correction to the channel cross section is $1 + 1 < 3 + 1 > %$ at $2.8 < 4.7 > \text{GeV}$. For $|t| < 0.02 \text{GeV}^2$ the scanning and WAP correction was performed by an extrapolation of the measured $t$ distribution for $|t| > 0.02 \text{GeV}^2$, assuming that the $t$ distribution is of the form $\exp (At)$, with $A$ depending on $M_{\pi\pi}$.

The combined correction is $-0.4 \pm 0.4 < 3.4 \pm 0.5 > %$ at $2.8 < 4.7 > \text{GeV}$.

Scanning losses were found to be $< 1\%$ for other topologies except for one prongs and strange particle decays.

B. Total and Topological Cross Sections

Using the numbers of events in Table II and the corrections of Table IV we obtain the total and topological cross sections given in Table V. The 1-prong cross section is based on 10% of the exposure.$^1$

Our total cross sections are in excellent agreement with other photo-production experiments,$^{19,21,22}$ but are systematically ($\sim 10\%$) lower than those from electron scattering.$^{23}$

C. Channel Cross Sections

In this section we divide the above topological cross sections into cross sections for various channels (leading to three-constraint, zero-constraint and under constrained fits). In the process the unmeasurable and unmeasured events of Table II are distributed among the different channels in the same proportions as the measurable events.
1. Three-constraint Reactions

The reactions

\[ \gamma p \rightarrow p^+ \pi^- \]

\[ \gamma p \rightarrow pK^+K^- \]

\[ \gamma p \rightarrow pp\bar{p} \]

\[ \gamma p \rightarrow p\pi^+\pi^+\pi^-\pi^- \]

\[ \gamma p \rightarrow pK^+K^-\pi^+\pi^- \]

\[ \gamma p \rightarrow p\pi^+\pi^+\pi^-\pi^- \]

have only the beam energy unknown, and they were selected by requiring that the three-constraint kinematic fit had \( \chi^2 < 30 \) and that the mass assignments were consistent with the observed ionization. The application of these selection criteria left only a small number (< 1%) of ambiguities between competing 3-C hypotheses. The numbers of 3-C fits selected are given in Table II.\(^{24,25}\)

Cross sections were determined using the fiducial volume, energy, and scanning corrections in Table VI. The cross sections for \( K^+K^- \) production include visible \( K^+ \) or \( K^- \) decays. The results are given in Table VIII. The cross sections for \( p\pi^+\pi^- \), \( pK^+K^- \) and \( pp\bar{p} \) are also shown in Fig. 4 together with results from previous bubble chamber experiments.\(^{11,26,27,28}\) Our results agree well with those of other experiments.

2. Zero-Constraint Reactions

We now discuss the cross section determination for channels with one or more neutral reaction products, which have zero kinematic constraints or are underconstrained. The experimental sample consists of all events which did not have an acceptable 3-C fit. We describe in detail the technique employed for the three-prong topology. Other topologies were analyzed using a similar technique.
For the three-prong topology we determine the cross sections for the channels

\[ \gamma p \rightarrow p\pi^+\pi^-\pi^0, \]  
\[ \rightarrow p\pi^+\pi^- + \text{(neutrals)}, \]  
\[ \rightarrow n\pi^+\pi^-\pi^- \]  
\[ \rightarrow n\pi^+\pi^- + \text{(neutral(s))}. \]

In order to separate the channels, events were "fitted" to hypotheses a and c and, for each hypothesis, a beam momentum was calculated. Channels b(d) when fitted as a(c) will yield too low a beam momentum. A "fit" of hypothesis c to an event of channel a may yield too high a beam momentum; these high beam momentum hypotheses were partially eliminated by rejecting interpretations with beam momentum, \( K_{\text{calc}} \), such that

\[ \frac{K_{\text{calc}} - K_{f}}{\delta K_{\text{calc}}} > 5, \]

where \( K_{f_{\text{max}}} \) is the maximum beam momentum (\( \sim 3.0 < 5.0 \) GeV at 2.8 < 4.7 > GeV; see equation 1 of Sec. II-A) and \( \delta K_{\text{calc}} \) is the error in \( K_{\text{calc}} \).

Events with acceptable 0-C "fits" were subdivided into two classes depending on the observed bubble density. (1) The \underline{unique} class in which either a proton was identified or all tracks were identified as pions. (2) The \underline{ambiguous} class containing all other events. Both the unique and ambiguous classifications include a small number of events with \( K^\pm \) tracks which could not be identified by bubble density.

The separation into \underline{single neutral particle} and \underline{multiple neutral particle} channels was made using missing mass plots. We used the measured
average photon energy to calculate the neutral missing mass, \( MM \), recoiling against the charged particles. The MM distributions for unique and ambiguous three and five-prong events are shown in Figs. 5 and 6. The distributions for \( \gamma p \rightarrow p \pi^+ \pi^- \) MM and \( \gamma p \rightarrow \pi^+ \pi^+ \pi^- \) MM show clear peaks at \( MM^2 = M_{\pi^0}^2 \) and \( MM^2 = M_n^2 \), respectively.

In order to obtain cross sections for \( \gamma p \rightarrow p \pi^+ \pi^- \pi^0 \) and \( \gamma p \rightarrow n \pi^+ \pi^+ \pi^- \) it is necessary to determine the shape and magnitude of the background contributions to the missing mass plots. The backgrounds fall into two main classes: (1) the contamination of \( n \pi^+ \pi^+ \pi^- \) by \( p \pi^+ \pi^- \pi^0 \) and vice versa, (2) the contamination of a four-body channel by five- and six-body channels. Backgrounds of type (1) were estimated from scatter plots of missing mass from \( p \pi^- \) MM vs. the missing mass from \( \pi^+ \pi^- \pi^+ \pi^- \) MM. In the calculation of type (2) backgrounds we used information from the five-prong channels \( p \pi^+ \pi^- \pi^+ \pi^- \), \( p \pi^+ \pi^- \pi^+ \pi^- \pi^0 \) and \( n \pi^+ \pi^+ \pi^- \pi^- \). We assumed that a \( \pi^+ \pi^- \) pair is equivalent to a \( \pi^0 \pi^0 \) pair (\( \rho^0 \) production is not important when averaged over all \( \pi^+ \pi^- \) combinations) and that \( \pi^- p \) approximates \( \pi^0 n \). Thus omitting in turn each \( \pi^+ \pi^- \) pair from \( p \pi^+ \pi^- \pi^+ \pi^- \) we recalculated the event as \( p \pi^+ \pi^- \) MM. Similarly, \( p \pi^- \pi^+ \pi^- \pi^+ \pi^- \pi^0 \) gives \( p \pi^- \pi^+ \pi^- \pi^0 \pi^0 \), \( \pi^+ \pi^- \pi^+ \pi^- \pi^- \pi^0 \) gives \( \pi^+ \pi^- \pi^+ \pi^- \pi^- \pi^0 \), and \( \pi^+ \pi^- \pi^+ \pi^- \pi^- \pi^0 \) gives \( \pi^+ \pi^- \pi^+ \pi^- \pi^- \pi^0 \) (the parentheses show the omitted particles).

To determine the overall shape of the combined backgrounds it is necessary to estimate the relative weights of the 5 and 6-body reactions. We used our five-prong data and a statistical model, the isospin weights for which are given in Table 11 of Ref. 29. The weights were derived assuming that the initial \( \gamma p \) state is equivalent to \( \left[ \rho^0 p \right] = \frac{2}{3} \left[ I = \frac{3}{2} \right] - \frac{1}{3} \left[ I = \frac{1}{2} \right] \) and neglecting resonance production in the final state. The relative
charge distribution among N-body states can then be derived, e.g., the expected ratio of $p^+ p^+ p^- p^- : p^+ p^- p^0 p^0 : n^+ n^+ n^- n^0$ is $20:32:36$. Similar ratios are derived for six-body final states. 29

We now discuss the characteristics of the backgrounds for each channel, considering the $n^+ n^+ n^-$ channel in greatest detail since the background is more important for this channel than for the $p^+ p^- n^0$ channel.

a. $n^+ n^+ n^-$

Figure 5 shows that neutron missing mass peaks occur in both the unique and ambiguous events. For the unique events we used a background of unique $n^+ n^+ n^- n^0$ and unique $n^+ n^+ n^- n^0$ added in the ratio predicted by the model. We then normalized this background to the number of events with $MM^2 > 1.15$ GeV$^2$. Normalization factors of $1.3 < 1.5$ relative to the predictions of the model were required at $2.8 < 4.7$ GeV, i.e., there is apparently more background from these channels than is predicted by the model. As can be seen from Fig. 5 the predicted $MM^2$ shape above the neutron peak agrees with the data.

The ambiguous $n^+ n^+ n^-$ events present more problems since there are two forms of background, namely: that discussed above for the unique channel, and that arising from ambiguous $p^+ p^- n^0$ and ambiguous $p^+ n^- +$ (neutrals). The ambiguous $p^+ p^- n^0$ background was estimated quantitatively from $MM^2$ scatterplots. 15 It yields a small contribution which peaks at missing masses below $M_n$. The shape of the ambiguous $p^+ p^- +$ (neutrals) background was obtained from the five-prong events using the model. The two types of multineutral backgrounds, namely those with a proton and those with a neutron, can be added either in the ratios predicted

- 15 -
by the model or in these ratios multiplied by the normalizations of the corresponding unique multineutral backgrounds. We used a background corresponding to the average of these procedures, although the background shape does not depend strongly on the procedure used. The combined multineutral background thus obtained was normalized to the high \( \text{MM}^2 \) data as before. Figure 5 shows that these backgrounds provide a good description of the \( \text{MM}^2 \) shape above the neutron peak. Cross sections for the channel \( \pi^+ \pi^+ \pi^- \) were obtained by counting the number of events above background up to a \( \text{MM}^2 \) of \( 1.2 \text{ GeV}^2 < 1.4 \text{ GeV}^2 \) for \( 2.8 \text{ GeV} < 4.7 \text{ GeV} \) and using Monte Carlo calculations\(^3_0\) to estimate the number of \( \pi^+ \pi^+ \pi^- \) events above the limit.

Cross sections for multiple neutral production were obtained from the unique events by subtracting the estimated single neutral production cross section from the total unique cross section. To this cross section was added that corresponding to the ambiguous events divided between the channels in the ratio used in the background calculation described above. Corrections were applied for events produced by low energy photons, strange particle contamination, scanning losses, and Dalitz pairs;\(^{15}\) these corrections are given in Table VII. The channel cross sections are given in Table VIII. The errors given in Table VIII include an uncertainty of \( \pm 50\% \) in the amount of background.

b. \( \pi^+ \pi^- \pi^0 \)

From Fig. 5 it can be seen that most of the \( \pi^0 \) peak is in the unique events. Consequently the background determination is simpler than for the \( \pi^+ \pi^+ \pi^- \) channel. Background shapes were determined separately for the unique and ambiguous fits and were normalized to the missing mass
distribution for $MM^2 \geq 0.2 \text{ GeV}^2$. Normalization factors of $\sim 3.0 < 2.0 >$
relative to the prediction of the statistical model were required at $2.8 < 4.7 >$
GeV for the unique events. Cross sections for single $\pi^0$ production were
obtained from the number of events above background with $MM^2 < 0.15 \text{ GeV}^2$.
Corrections for the high $MM^2$ tail and $\pi^0$ events from low energy photons
were made using Monte Carlo calculations. These calculations showed
that the $\pi^0$ peak should be symmetric within statistics. Therefore, the
number of $\pi^0$ events with $MM^2 > 0.15 \text{ GeV}^2$ was estimated from the number
of $\pi^0$ events with $MM^2 < -0.11 \text{ GeV}^2$. Cross sections for the $p\pi^+\pi^- +$ neutrals
channel were obtained in the same manner as for the $n\pi^+\pi^-\pi^- +$ neutral(s)
channel. Corrections for low energy events, strange particle contamination,
scanning losses and Dalitz pairs are given in Table VII. Cross sections
are given in Table VIII; the errors, as before, include an uncertainty of
$\pm 50\%$ in the amount of background.

c. Comparison with other Experiments

Figure 7 shows the three-prong $0$-constraint cross sections together with cross sections from an experiment using an annihilation beam. We find good agreement between the experiments.

IV. THE REACTION $\gamma p \rightarrow p\pi^+\pi^-; \rho^0$ AND $\Delta^{++}$ PRODUCTION

A. Introduction and Mass Distributions

In this section we give general characteristics of the channel $\gamma p \rightarrow p\pi^+\pi^-$. In section II-D and III-A it was shown that event losses for this channel were less than 3\% for target to proton four-momentum transfers squared, $|t|$, greater than $0.02 \text{ GeV}^2$. Below $|t| = 0.02 \text{ GeV}^2$ events were lost due to
scanning biases; contamination by wide angle electron pairs also occurred. Consequently in this section we discuss only events with $|t| > 0.02 \text{ GeV}^2$. In addition, only events within the $E_y$ intervals given in Table I were used. In Fig. 8 (a)-(b) we show Dalitz plots for 2.8 GeV and 4.7 GeV, respectively. Chew-Low plots for $\pi^+\pi^-$, $p\pi^+$ and $p\pi^-$ are given in Fig. 9 (a)-(f). Mass projections with momentum transfer cuts for $\pi^+\pi^-$, $p\pi^+$ and $p\pi^-$ are shown in Fig. 10 (a)-(b). From these figures it is evident that the channel is dominated by peripheral $\rho^0$ and $\Delta^{++}$ production. We discuss in Sec. IV-B, C, D the characteristics of $\rho^0$ photoproduction and in Sec. IV-E $\Delta^{++}$ production. Upper limits for production of high mass vector mesons decaying into $\pi^+\pi^-$ are given in Sec. IV-F.

B. Model Independent Study of Dipion and $\rho^0$ Meson Production

1. Introduction

From Fig. 10 (a) it can be seen that the $\rho^0$ does not peak at the commonly accepted $\rho^0$ mass, does not have the shape of a p-wave Breit Wigner and changes shape as a function of $t$. Since cross sections for $\rho^0$ production cannot be deduced without the use of a model which explains this change of $\rho^0$ shape, we postpone the evaluation of $\rho^0$ cross sections to Sec. IV-C in which models of $\rho^0$ production are compared with the data.

In this section we make model-independent determinations of (a) the differential cross sections for the production of $\pi^+\pi^-$ pairs, (b) the characteristics of the $\pi^+\pi^-$ angular distribution, and (c) the cross section for the production of $s$-channel helicity-conserving $p$-wave $\pi^+\pi^-$ pairs.
2. Double Differential Cross Sections for Dipion Production in the \( \rho \) Region

In Table IX we give \( \Delta \sigma / \Delta t \Delta M \) for the production of all pion pairs of mass, \( M \), where \( \Delta M = 40 \) MeV, and for nine \( t \)-intervals in the range \( 0.02 < |t| < 0.4 \) GeV\(^2\). In this momentum transfer range the \( t \)-distribution is well represented by the form \( B e^{At} \) where \( B = d^2 \sigma / dt dM \bigg|_{t = 0} \) and we present in Fig. 11 the values of \( A \) and \( B \), obtained from a maximum likelihood fit, for intervals of the \( \pi \pi \) mass. The value of \( \int_{2m_\pi}^{1.08 \text{ GeV}} B \ dM \), corresponding to the production of all dipion pairs in the \( \rho^0 \) region, is \( 159 \pm 8 < 118 \pm 5 > \mu \text{b/GeV}^2 \) at \( 2.8 < 4.7 > \) GeV.

3. Formalism for the Analysis of the Dipion Angular Momentum States

We now discuss the angular distribution of pion pairs in the \( \pi^+ \pi^- \) rest system. As will be shown below the pion pairs are in a predominantly \( p \)-wave state, so for brevity we refer to them as \( \rho^0 \). We use the formalism of Refs. 34 and 35 which describes vector meson production by polarized photons.

We consider the angular distribution of \( \rho^0 \) decay in three reference systems which differ in the choice of the spin quantization axis (z axis): the Gottfried-Jackson system, where the z axis is the direction of the incident photon in the \( \rho^0 \) rest system; the helicity system, where the z axis is the direction of the \( \rho^0 \) in the overall \((\gamma p)\) c.m. system, i.e., opposite to the direction of the outgoing proton in the \( \rho^0 \) rest system; and the Adair system, where the z axis is along the direction of the incident photon in the overall \((\gamma p)\) c.m. system. The y axis is always normal to the production plane.\(^36\) For forward produced \( \rho^0 \) mesons, all three systems coincide.
Depending upon the production mechanism, the $\rho^0$ may be aligned in one of these three systems. The system which gives the simplest description of the $\rho^0$ is then: (1) the Gottfried-Jackson system for t-channel helicity conservation (resulting from, for example, $J^P = 0^\pm$ exchange with no absorption); (2) the helicity system for s-channel c.m.s. helicity conservation; (3) the Adair system for "spin independence" in the s-channel c.m.s.\(^{37}\) One of the objectives of the density matrix analysis of Sec IV-B is to determine the preferred system for describing $\rho^0$ photoproduction.

In all three systems the decay angular distribution for rho mesons produced by linearly polarized photons can be expressed in terms of nine independent measurable spin density matrix parameters $\rho_{\alpha \beta}^{34,35}$:

\[
W(\cos \theta, \phi, \psi) = \frac{3}{4\pi} \left[ \frac{1}{2}(1 - \rho_{00}^0) + \frac{1}{2}(3\rho_{00}^0 - 1)\cos^2 \theta - \sqrt{2} \Re \rho_{10}^0 \sin 2\theta \cos \phi \\
- \rho_{1-1}^0 \sin^2 \theta \cos 2\phi - P_Y \cos^2 \phi \left[ \rho_{11}^1 \sin^2 \theta + \rho_{00}^0 \cos^2 \theta \right] \\
- \sqrt{2} \Re \rho_{10}^1 \sin 2\theta \cos \phi - \rho_{1-1}^1 \sin^2 \theta \cos 2\phi \\
- P_Y \sin 2\phi \left[ \sqrt{2} \Im \rho_{10}^2 \sin 2\theta \sin \phi + \Im \rho_{1-1}^1 \sin^2 \phi \right] \right]
\]

Here, $P_Y$ is the degree of linear polarization of the photon; $\phi$ is the angle of the photon electric polarization vector with respect to the production plane measured in the overall (yp) c.m.s.; $\theta$ and $\phi$ are the polar and azimuthal angles of the $\pi^+$ in the $\rho^0$ rest frame (See Fig. 12 and footnote 36.) In terms of helicity amplitudes, $T_{k\ell, mn}$, the density matrix parameters are given by:\(^{34,35}\)
\[ \rho_{ik}^0 = \frac{1}{A} \sum_{\lambda' \lambda'' \lambda \lambda'} T_{\lambda'}^{\lambda''} \rho_{\lambda' \lambda''}^{\lambda} \rho_{\lambda'' \lambda}^{\lambda'} , \]
\[ \rho_{ik}^1 = \frac{1}{A} \sum_{\lambda' \lambda'' \lambda \lambda'} T_{\lambda'}^{\lambda''} \rho_{\lambda' \lambda''}^{\lambda} \rho_{\lambda'' \lambda}^{\lambda'} , \]
\[ \rho_{ik}^2 = \frac{i}{A} \sum_{\lambda' \lambda'' \lambda \lambda'} \lambda' T_{\lambda'}^{\lambda''} \rho_{\lambda' \lambda''}^{\lambda} \rho_{\lambda'' \lambda}^{\lambda'} , \]

with
\[ A = \sum_{\lambda' \lambda'' \lambda \lambda'} T_{\lambda'}^{\lambda''} \rho_{\lambda' \lambda''}^{\lambda} \rho_{\lambda'' \lambda}^{\lambda'} , \]

where \( \lambda', \lambda', \lambda'' \) denote the helicity of the outgoing proton, the photon, the target proton respectively and \( \lambda, \lambda' \) the helicity of the produced \( \rho \)-meson.

The matrix elements \( \rho_{ik}^0 \) describe the rho decay in the case of an unpolarized beam; the additional terms \( \rho_{ik}^1 \) and \( \rho_{ik}^2 \) are measurable with a linearly polarized photon beam. For further details see Appendix C.

It has been shown that to leading order in energy,\(^{38,39}\) the overall production cross section (\( \sigma \)) may be split into non-interfering contributions \( \sigma^N, \sigma^U \) from natural and unnatural parity exchange in the \( t \)-channel by linear combinations of the density matrix parameters.\(^{35}\)

We define \( P_\sigma \), the parity asymmetry, by

\[ P_\sigma = \frac{\sigma^N - \sigma^U}{\sigma^N + \sigma^U} . \]

At high energies

\[ P_\sigma = 2 \rho_{1-1}^1 - \rho_{00}^1 . \]
Note that $P_{\sigma}$ is invariant under rotations around the normal to the production plane; e.g., it is the same in the three systems described above. We also point out that $P_{\sigma}$ is sensitive to possible $\rho^0$ helicity or spin-flip terms (contributing to $\rho_{00}^1$) which are not usually measured in counter experiments. Counter experiments of the type of Refs. 40 and 41 measure the asymmetry $\Sigma$ defined as

$$\Sigma = \frac{\sigma_{\parallel} - \sigma_{\perp}}{\sigma_{\parallel} + \sigma_{\perp}} = \frac{\rho_{11}^1 + \rho_{1-1}^1}{\rho_{11}^0 + \rho_{1-1}^0}.$$  

Here $\sigma_{\parallel}$ and $\sigma_{\perp}$ are the cross sections for the pions from symmetric rho decay ($\theta = \pi/2$, $\phi = \pi/2$) to emerge in the plane of the photon polarization ($\phi = \pi/2$) and perpendicular to it ($\phi = 0$). When the helicity-flip terms, $\rho_{00}^1$, $\rho_{11}^1$, $\rho_{00}^0$, $\rho_{1-1}^0$ are zero, $\Sigma$ is equal to $P_{\sigma}$.

The $\rho^0$ decay distribution may be simplified if we use the angle $\Psi = \phi - \phi$ which, in the forward direction, is the angle between the photon polarization and $\rho^0$ decay plane. If the $\rho^0$ production mechanism conserves s-channel helicity, i.e., the rho is transverse and linearly polarized like the photon, then in the helicity system

$$\rho_{1-1}^1 = -\text{Im} \rho_{1-1}^2 = \frac{1}{2},$$

and all other $\rho_{ik}^{\alpha}$ in Eq. (2) = 0.

In these circumstances $\Psi$ is the azimuthal angle in the helicity system of the decay $\pi^+$ with respect to the $\rho^0$ polarization plane and the decay angular distribution is proportional to $\sin^2 \theta \cos^2 \Psi$. The distribution of $\Psi$ is also related to $P_{\sigma}$ if the helicity-flip terms are zero: for 100% linear polarization the
decay is \( \sin^2 \theta \cos^2 \Psi \) for \( P_\sigma = +1 \) while for \( P_\sigma = -1 \) the decay distribution is \( \sin^2 \theta \sin^2 \Psi \).

4. The Moments, \( Y^m_l \), of the Dipion System

Figure 13 shows the distributions of the polar angle \( \theta \) and the angle \( \Psi \) in the helicity system for events in the \( \rho^0 \) mass region (0.60 - 0.85 GeV) with \( |t| < 0.4 \text{ GeV}^2 \). This figure shows that the \( \rho^0 \) decay has a simple description in terms of \( \theta \) and \( \Psi \) in the helicity system viz. the \( \rho^0 \) is well described by a \( \sin^2 \theta \cos^2 \Psi \) angular distribution for \( |t| < 0.4 \text{ GeV}^2 \). Consequently, in order to give an overall description of the characteristics of the decay angular distribution of the \( \pi^+ \pi^- \) system, we present in Fig. 14 the moment sums, \( \sum \text{Re} Y^m_l (\theta, \Psi) \), of the \( \pi^+ \pi^- \) system in the helicity frame as a function of \( \pi^+ \pi^- \) mass for \( |t| < 0.4 \text{ GeV}^2 \). Only those moments are shown which have a significant deviation from zero in either the 2.8 or 4.7 GeV data; other moments can be found in Ref. 17. From the moments we conclude that:

a. Strong \( Y^0_2 \) and \( Y^2_2 \) moments are present in the \( \rho^0 \) region which follow the asymmetric \( \rho^0 \) shape. This and the small values of higher even moments demonstrates that it is the p-wave part of the mass spectrum that is skewed.

b. Odd moments, \( Y^0_1, Y^0_3 \) are present throughout the dipion mass range. These moments are due to differences in the \( \pi^+ p \) and \( \pi^- p \) mass spectra and consequently they result mainly from \( \Delta^{++} \) production. In addition, \( \Delta^{++} \) production gives rise to the positive \( Y^0_2 \) moment at large \( \pi^+ \pi^- \) masses.
c. At 4.7 GeV, evidence exists for a $\Upsilon_4^0$ moment which changes
sign through the $\rho^0$ region. This moment may be interpreted as originating
from the interference of the $\rho^0$ with angular momentum states with spin
\geq 3.

d. No significant moments, other than those associated with a
p-wave system or the $\Delta^{++}$, exist in the $\rho^0$ region. This indicates a negligible
incoherent background under the $\rho^0$.

5. The Density Matrix Elements of the Dipion and $\rho^0$ States:

Determination of $\rho^0$ Production Properties

In the previous section we found that, with the exception of $\Delta^{++}$
reflections, the $\pi\pi$ angular distributions are p-wave dominated. We therefore use the p-wave formalism of Eq. (2) and show in Fig. 15 the helicity
frame density matrix elements and $P_\sigma$, determined by the method of moments,
as a function of $\pi\pi$ mass. These plots indicate that the $\rho^0$ region is charac-
terized by $P_\sigma \simeq 1$ and $\rho_1^{1-1} \simeq -\text{Im } \rho_1^{2-1} \simeq 0.5$ with other $\rho_\alpha^{\alpha}$ close to zero
(see Eq. (6)). Deviations from these values become apparent at high $\pi\pi$
masses where we observe primarily the $\Delta^{++}$ reflection. Deviations at low
$\pi\pi$ masses are discussed in Sec. IV-C2.

We have determined the density matrix elements for the rho
taking the background into account through a maximum likelihood fit including $\rho^0$, $\Delta^{++}$ and phase space contributions. (See Appendix A.) This method
was checked by evaluating the $\rho_\alpha^{\alpha}$ by the method of moments inside and out-
side of the rho region and estimating the contribution of the background from
the values outside the $\rho^0$ region. Within errors, the same results were
obtained.\textsuperscript{42} Even if all events in the mass region $0.60 < M_{\pi\pi} < 0.85$ GeV
are used without background subtraction the values of the \(\rho_{ik}^{\alpha}\) do not change by more than at most one standard deviation, indicating that the rho density matrix parameters, with the present errors, are insensitive to the assumed form of the background.

Figure 16 and Table X show the density matrix parameters evaluated in the Gottfried-Jackson, helicity and Adair systems as a function of \(t\). Note that the rho density matrix elements can be expressed in terms of bilinear combinations of helicity or spin amplitudes and that, for example, \(\rho_{00}^0\) and \(\rho_{00}^1\) receive contributions only from rho helicity-flip or spin-flip amplitudes (c.f., Eq. (3), Appendix C and Ref. 35).

We conclude from the behavior of the \(\rho_{ik}^{\alpha}\):

1. The density matrix parameters vary rapidly with \(t\) in the Gottfried-Jackson system. The \(t\)-channel helicity-flip amplitudes increase rapidly with increasing \(|t|\). This behavior rules out \(t\)-channel helicity conservation.\(^{10,11}\)

2. The \(\rho_{ik}^{\alpha}\) in the Adair system also vary significantly with \(t\). This excludes the hypothesis of spin independence in the total c.m. system for rho production.\(^{37}\)

3. In the helicity system the rho helicity-flip contributions are zero within errors up to \(|t| = 0.4\ \text{GeV}^2\). In other words, the rho production mechanism is consistent with the conservation of \(s\)-channel c.m.s. helicity for \(|t| < 0.4\ \text{GeV}^2\). More specifically, we have shown that there is no significant helicity-flip at the \(\gamma p\) vertex; in the absence of a measurement of the nucleon polarization we cannot determine whether the nucleon vertex conserves helicity. There are indications that \(s\)-channel helicity is conserved in \(\pi p\) elastic scattering however;\(^{43}\) factorization would then suggest that
s-channel helicity conservation holds overall for the reaction $\gamma p \rightarrow p\rho^0$. However, we must point out that while our data are consistent with helicity conservation at the $\gamma p$ vertex, within errors there is still room for an admixture of $\rho^0$ helicity-flip amplitudes. \textsuperscript{44}

The fact that the helicity-flip contributions are at a minimum in the helicity system is further demonstrated in Fig. 17. A maximum likelihood fit was made to determine the angle $\beta$ through which a density matrix, corresponding to no helicity-flip, must be rotated to give the best fit to the angular distribution in the helicity frame. \textsuperscript{45} Figure 17 shows $\beta$, measured about the normal to the production plane, as a function of $t$ together with lines indicating where the data points should fall if the flip terms were minimal in the Gottfried-Jackson (G. J.), helicity (H), Adair system (A). For $|t| < 0.4 \text{ GeV}^2$, the helicity system is clearly preferred; at larger $|t|$ some s-channel helicity-flip amplitudes seem to be present.

In Fig. 18 $P_{\sigma}$ and $\Sigma$ are shown as a function of $t$. We see that rho production is completely dominated by natural parity exchange up to $t = 1 \text{ GeV}^2$. Averaging $P_{\sigma}$ over the range $|t| \leq 1 \text{ GeV}^2$ we find the contribution from unnatural parity exchange to be $3.1 \pm 3.1 < -1.1 \pm 2.8 > \%$ at $2.8 < 4.7 > \text{ GeV}$. Our values of $\Sigma$ are in agreement with measurements made at DESY and Cornell. \textsuperscript{40, 41}

In summary, rho photoproduction via $\gamma p \rightarrow p\rho^0$ proceeds almost completely through natural parity exchange and is consistent with helicity conservation in the $s$-channel c.m. system up to $|t| = 0.4 \text{ GeV}^2$. Furthermore, $t$-channel helicity conservation and "spin independence" in the c.m. system are clearly ruled out.
6. Cross Section for s-channel Helicity-conserving p-wave Dipion States

In order to obtain a cross section for p-wave dipion production in the $\rho^0$ mass region it is necessary either to determine directly the amount of p-wave present from an analysis of the $\pi\pi$ angular distribution or, from a knowledge of the $\rho^0$ mass shape, to deduce which part of the $\pi\pi$ mass spectrum is $\rho^0$. The latter procedure requires the use of a model to describe the $\rho^0$ mass shape in photoproduction and is discussed in Sec. IV-C. Here, we determine a model-independent cross section for p-wave $\pi\pi$ pairs. We make use of the result of the previous section that the production mechanism for p-wave $\pi\pi$ pairs conserves s-channel helicity at the $\gamma\pi\pi$ vertex for $|t| < 0.4 \text{ GeV}^2$ and so yields pion pairs in a well defined spin state. This implies (see Section IV-B3) that the decay angular distribution for p-wave pion pairs is given in the helicity system by

$$W(\theta, \psi) = \frac{3}{8\pi} \left| \sin^2 \theta + P_\gamma \sin^2 \theta \cos 2\psi \right|$$

which may be expressed in terms of spherical harmonics as

$$W(\theta, \psi) = \frac{1}{\sqrt{4\pi}} Y^0_0(\theta) - \frac{1}{\sqrt{20\pi}} Y^0_2(\theta) + 2P_\gamma \sqrt{\frac{3}{40\pi}} \text{Re} \ Y^2_2(\theta, \psi).$$

$Y^2_2$ is least affected by background due to its $\psi$ dependence. Consequently we have determined $\Pi$, the s-channel helicity-conserving p-wave cross section from

$$\Pi = \frac{1}{P_\gamma} \sqrt{\frac{40\pi}{3}} \Sigma \text{Re} \ Y^2_2 = \frac{2.5}{P_\gamma} \Sigma \sin^2 \theta \cos 2\psi$$

where the summation is over all events.
The dots marked on the histograms of Fig. 10 show \( \Pi \) as a function of \( M_{\pi\pi} \) for different \( t \) intervals. We notice that in the \( \rho^0 \) region \( \Pi \) accounts for nearly all events and is zero within errors above \( M_{\pi\pi} = 1 \) Gev. This shows that the background does not contribute to \( Y_2^2 \) and indicates the absence of high mass helicity-conserving p-wave states. The total helicity-conserving p-wave cross section (corrected for the interval \( |t| < 0.02 \text{ GeV}^2 \)) is given in Table XI; the differential \( \Pi \) cross section is given in Table XII and Fig. 19. We emphasize that \( \Pi \) is not necessarily a \( \rho^0 \) cross section since non-resonant, helicity conserving, p-wave \( \pi\pi \) pairs may be present as a coherent background.

C. Determination of the \( \rho^0 \) Production Cross Section by the Use of Models

1. The Ross-Stodolsky Model

The Ross-Stodolsky model suggests that the \( \rho^0 \) Breit-Wigner should be multiplied by the factor \( (M_{\rho}/M_{\pi\pi})^4 \) to explain the mass shift for small \( |t| \) (Sec. IV-B1). In order to test this we have made a maximum likelihood fit (described in Appendix A) in which the \( \rho^0 \) Breit-Wigner form (Eq. (2) of Appendix A) is multiplied by \( (M_{\rho}/M_{\pi\pi})^n \). We have determined \( n \) for different \( t \) intervals using fitted values \( M_{\rho} = 764 \) MeV and \( \Gamma_{\rho} = 143 \) MeV. These values for the \( \rho^0 \) mass and width were obtained by a fit to all events with \( 0.02 < |t| < 0.4 \text{ GeV}^2 \) allowing for a linear variation of \( n \) with \( t \). Figure 20 shows \( n \) as a function of \( t \). We find that \( n \gtrsim 5 \) for \( t \approx 0 \) and reduces to zero for \( |t| > 0.5 \text{ GeV}^2 \). From this we conclude that a \( t \)-independent Ross-Stodolsky factor multiplied into a p-wave Breit-Wigner does not describe the data. However, as seen from Fig. 10 our parameterization with \( t \)-dependent exponent does provide a good description of the mass
spectrum. Consequently, we may use this parameterization to fit the 
\[ \gamma p \rightarrow p
^+\pi^- \] Dalitz plot and determine the amount of phase space-like back-
ground and \( \Delta^{++} \) production; further, by assuming that the remaining part
of the channel is \( \rho^0 \) we can deduce a \( \rho^0 \) cross section which we refer to as
the parameterization cross section. We have checked that the parameteri-
zation cross section is insensitive to the Breit-Wigner form used and to
variations of \( n \) by \( \pm 1 \); in fact, a constant \( n = 4 \) gives essentially the same \( \rho^0 \)
cross section. Consequently, the parameterization cross sections may be
directly compared with previous track chamber results.

The total and differential parameterization cross sections are
given in Tables XI and XII, respectively, and the differential cross section is
plotted in Fig. 19.

2. The Söding Model

The Söding model explains the \( \rho^0 \) mass shift in terms of an in-
terference between a diffractively produced \( \rho^0 \) and a Drell type background. \[ 48,49 \]
The details of the model are given in Appendix B. In applying the model to
our data we have made the following modifications to the original version of
the model: \[ 49 \]

1. The direct \( \rho^0 \) production was made s-channel helicity-
conserving in order to agree with our experimental observations.

2. We added incoherently into the Drell term those \( \pi p \) scat-
tering amplitudes that result in a spin-flip of the proton.

3. It has recently been pointed out that in adding the p-wave part
of the Drell term to the \( \rho^0 \) "doubling counting" may occur. This can be avoided
by adding a rescattering term to the Drell background which is equivalent to
multiplying the Drell amplitude by $e^{i\delta} \cos \delta$ where $\delta$ is the phase shift for $I = 1, \ell = 1$ $\pi \pi$ scattering. All Söding model calculations in this paper use this correction. The addition of the rescattering term introduces an ambiguity into the definition of the $\rho^0$ cross section. The $\rho^0$ amplitude may be defined either as that resulting from the direct diffractive process (diagram (a) of Fig. 29), or, as the sum of this amplitude and the rescattering term (diagram (c) of Fig. 29); this point is discussed in more detail in Appendix B. The cross sections given in the text originate from the first definition of the $\rho^0$ amplitude. For cross sections using the second definition see Appendix B.

4. As will be discussed below, $\Delta^{++}$ production cannot be entirely accounted for by a simple OPE diagram like the Drell term; consequently, the $\Delta^{++}$ was taken out of the Drell term and was fitted incoherently.

5. In calculating the Drell term, we tried different form factors for the $\pi-p$ vertex, namely, the Ferrari-Selleri form factor, the Benecke-Dürr form factor and no form factor. The $\rho^0$ masses, widths and cross sections given in this section are from fits with the Ferrari-Selleri form factor. Results from the other fits are given in Appendix B.

In applying the model to the data we first determined the $\rho^0$ mass, $M_{\rho}$, its width, $\Gamma_{\rho}$, and the slope, $A$, of the momentum transfer distribution in the interval $0.02 < |t| < 0.4 \text{GeV}^2$. In this fit we varied the amount of Söding amplitude, $a_s$ (see Eq. (1) of Appendix B), the ratio of the $\rho^0$ to Drell amplitudes, $Y$, and the amount of $\Delta^{++}$. We found $M_{\rho} = 767 \pm 4 <770 \pm 4> \text{MeV}$, $\Gamma_{\rho} = 145 \pm 10 <155 \pm 10> \text{MeV}$, and $A_{\rho} = 6.0 \pm 0.3 <6.3 \pm 0.3> \text{GeV}^{-2}$ at $2.8 <4.7> \text{GeV}$. In subsequent calculations in smaller momentum
transfer intervals, $M_{\rho}$, $\Gamma_{\rho}$ and $A_{\rho}$ were held constant at the values given above and $a_{s}$, $Y$, and the amount of $\Delta^{++}$ were fitted. The fitted values of the ratio of $\rho$ to Drell cross sections, $\sigma_{\rho}/\sigma_{D}$, derived from $Y$, are shown in Fig. 21 as a function of $t$. The curves give the $t$ dependence of $\sigma_{\rho}/\sigma_{D}$ calculated using the absolute prediction of the Drell intensity and the fitted total $\rho^{0}$ cross section, $\sigma_{\rho}$. The ratio $\sigma_{\rho}/\sigma_{D}$ as given by the model is too small by a factor of two for the Ferrari-Selleri form factor used here, while it is approximately correct for the Benecke-Dürr form factor.

The Söding model describes well the $\pi^{+}\pi^{-}$ mass shapes and their variation with $t$ (solid lines of Fig. 10a) and consequently the related dependence of the exponential slope of the $t$-distribution on the $\pi^{+}\pi^{-}$ mass (solid lines of Fig. 11c, d). The solid lines in Figs. 14 and 15 show the moments, and $\rho_{\text{ik}}$ predicted by the model. The predicted moments agree well with the data. We note that the shape of the $Y_{4}^{0}$ moment is reproduced by the model indicating that the Drell term describes well both the $1^{-}$ and $3^{-}$ backgrounds in the $\rho^{0}$ region. Figure 15 shows that the model accounts for the variation of $\rho_{\text{ik}}$ as a function of $\pi\pi$ mass; the behavior of the $\rho_{\text{ik}}$ below (above) the $\rho^{0}$ peak is mainly determined by the Drell term ($\Delta^{++}$ reflection).

We have calculated the dipion density matrices for the Söding model in the region $|t| > 0.4$ GeV$^{2}$ and have found that the model does not account for the lack of helicity conservation in this region. In the framework of the model, therefore, we attribute the lack of helicity conservation of the dipion system at large $|t|$ to the $\rho^{0}$ production mechanism rather than to the influence of the Drell, $\Delta^{++}$ and phase space background terms.

The total and differential $\rho^{0}$ cross sections obtained by fitting the Söding model to our data are given in Tables XI and XII, and in Fig. 19. The errors shown are statistical and do not reflect the uncertainties inherent in the model. These uncertainties are discussed in the following section.
Two features should be noted, namely, that the differential cross section for $\rho^0$ production at $t = 0$, and the slope of the momentum transfer distribution, are both lower than those obtained from $\Pi$ or the parameterization method.

3. A Phenomenological Check of the Soding Model Cross Sections

The question now arises as to how much the Soding model cross sections and slopes may be in error due to uncertainties in the Soding model. Some of these uncertainties are as follows: (a) lack of knowledge of the $\rho^0$ shape; (b) lack of knowledge of the $\pi p$ form factor; (c) possible corrections to make the model gauge invariant; (d) the possibility of exchanges other than one pion exchange (as will be shown in Sec. IV-E exchanges other than OPE are needed to explain $\Delta^{++}$ production). Point (b) was checked by repeating the fits with the Benecke-Dürre form factor and with no form factor. Although this resulted in changes in the fitted $\rho^0$ width, the forward $\rho^0$ cross section and the $\rho^0$ mass remained the same within one standard deviation (see Appendix B). Uncertainties (c) and (d) imply that the Drell background may be unknown to a greater extent than allowed for by form factor variation.

Uncertainties (a) - (d) lead us to an alternative, more phenomenological approach. If the $\rho^0$ mass, $M_\rho$, and width, $\Gamma_\rho$, are taken from other experiments, the $\rho^0$ cross section may be deduced from the value of the double differential cross section for dipion production at $M = M_\rho$, since the rescattering correction (Fig. 29c) implies that the $p$-wave part of the Drell background should vanish at the $\rho$ mass.

To determine the $\rho^0$ cross section at $t = 0$ using this method we have: (a) Fitted a smooth interpolation curve of the form Breit-Wigner.
(M_\rho/M_{\pi\pi})^n \text{ to the dipion cross section } d^2\sigma/dtdM_t = 0 \text{ of Table IX for dipion pairs in the region } 0.6 < M_{\pi\pi} < 0.9 \text{ GeV. In the fit we varied } n \text{ and the mass and width of the } \rho^0. \text{ As seen from Fig. 11 (a)-(b), this gives a good fit to the data at both energies.} (b) Selected a mass and width for the } \rho^0 \text{ and calculated the } \rho^0 \text{ forward differential cross section from}

\frac{d\sigma}{dt} = (d^2\sigma/dtdM)^{M=\rho} \pi \frac{\Gamma}{\rho/2} \quad (8)

where we take } d^2\sigma/dtdM \text{ from the fitted curve obtained in step (a).}

Figure 22 shows the } \rho^0 \text{ forward cross section obtained by this method plotted as a function of the mass and width of the } \rho. \text{ These curves show that the } \rho \text{ forward differential cross section can vary from } 106 \mu b/\text{GeV}^2 \text{ to } 155 \mu b/\text{GeV}^2 \text{ at } 2.8 \text{ GeV (74 } \mu b/\text{GeV}^2 \text{ to } 118 \mu b/\text{GeV}^2 \text{ at } 4.7 \text{ GeV) using the range of } \rho^0 \text{ masses (775-755 MeV) and widths (110-147 MeV) found in}\text{ the Review of Particle Properties. With the values of } M_\rho, \Gamma_\rho \text{ obtained in Sec. IV-C2, we find } 148 \pm 12 < 109 \pm 8 > \mu b/\text{GeV}^2 \text{ at } 2.8 < 4.7 > \text{ GeV. These values are significantly larger than those resulting from our Söding model fits (Table XI). Two effects are responsible for this. Firstly, we have not subtracted background. From the extrapolated cross section outside the } \rho^0 \text{ region we estimate the background to be } \sim 8 < 2 > \% \text{ at } 2.8 < 4.7 > \text{ GeV.} \text{ Secondly, in the Söding model fits the rho cross section is obtained by integrating the rho Breit-Wigner over the available phase space; at low } |t| \text{ the area of the Breit-Wigner is reduced relative to that at large } |t|, \text{ in contrast to the constant area implicit in Eq. (8). Consequently Eq. (8) gives larger cross sections at low } |t| \text{ than do the Söding model fits.}

We have applied Eq. (8) to a series of } t\text{-bins in the } 0.02 < |t| < 0.5 \text{ GeV}^2 \text{ region (using, of course, } t\text{-independent } M_\rho, \Gamma_\rho). \text{ The}
differential cross sections obtained with $\Gamma_\rho$ set equal to the values found in the Söding model fits, viz. $145 < 155 > \text{MeV}$ at $2.8 < 4.7 > \text{GeV}$, and $M_\rho = 770 \text{ MeV}$, are given in Table XIII. With the exception of the $|t|$ interval $0.02 - 0.075 \text{ GeV}^2$, where phase space effects are important, the values of Table XIII agree well with those of Table XII. The cross sections of Table XIII are proportional to the assumed rho width and show approximately the same dependence on the $\rho^0$ mass as is illustrated in Fig. 22. Figure 11 shows that the slope of the $\rho^0$ differential cross section obtained using Eq. (8) is independent of $\rho^0$ masses lying within the currently accepted range.\textsuperscript{57}

We conclude that:

1. The size of the Söding model forward differential cross section as determined in this section depends on the mass and width of the $\rho^0$, being lowest for a high mass and a small width of the $\rho^0$;

2. The lack of knowledge of the $\rho$ mass and width, and of the form of the Drell background, implies that Söding model cross sections as given in this and the preceding section are uncertain to about $\pm 20\%$.

We emphasize that the procedure, outlined above, for checking the Söding model has determined $\rho^0$ cross sections from the rho amplitude at $M = M_\rho$; these $\rho^0$ cross sections depend neither on the details of the rho shape nor on the available phase space.

4. Other Models

Several models have been put forward recently to describe $\rho^0$ photo-production, none, however, describes quantitatively all aspects of the data.

The dual resonant model of Satz and Schilling\textsuperscript{58} describes correctly the $\rho^0$ mass shape and its variation with momentum transfer, but
predicts that the $\rho^0$ conserves t-channel helicity in contrast to the experimentally observed s-channel helicity conservation; also the $Y_4^0$ interference term predicted by the model has the wrong sign.

The model of Kramer and Quinn\(^\text{59}\) calculates $\rho^0$ photoproduction using diagram (c) of Fig. 29. We have not made a detailed comparison with this model but we have compared our data in the $|t|$ interval $0.02 - 0.4 \text{ GeV}^2$ to an approximate form given by Kramer.\(^\text{60}\) We find that in order to fit the mass spectrum we require a large width for the $\rho^0$ (170 to 180 MeV) and that the fit is poor ($\chi^2$ of 145 for 48 degrees of freedom compared with a $\chi^2$ of 65 for 48 degrees of freedom for the Söding model at 4.7 GeV). The model predicts that the $\rho^0$ conserves s-channel helicity and describes well the variation of the dipion density matrix elements, $\rho^0_{ik}$, with mass.

Rho photoproduction has also been discussed using a Regge pole model by Mannheim and Maor.\(^\text{61}\) They suggest that the $\rho^0$ Breit-Wigner should be multiplied by $(M_\rho/M_{\pi\pi})^4$ at $t = 0$ but do not predict a specific form for the variation of $\rho^0$ shape with momentum transfer.

Greenhut\(^\text{62}\) has suggested that the $\rho^0$ mass skewing is due to an isoscalar s-wave dipion background; this is incompatible with the moments shown in Fig. 14.

In conclusion, the Söding model gives a good quantitative description for $|t| < 0.4 \text{ GeV}^2$ of the $\rho^0$ mass shape and its variation with momentum transfer, the variation of the dipion density matrix elements with dipion mass, and the moments of the dipion system. This model implies that not all p-wave dipion pairs are resonant since dipion pairs originate in part from the Drell term. The Kramer-Quinn model describes the features of $\rho^0$ photoproduction qualitatively. This model suggests that all p-wave dipion pairs should be
interpreted as \( \rho^0 \), hence the \( \rho^0 \) cross sections would be given by \( \Pi \) or by the parameterization cross section.

5. Comparison with other Experiments

Previously published cross sections for \( \rho^0 \) photoproduction on hydrogen have been obtained using three different techniques:

1. detection of symmetric \( \pi^+ \pi^- \) pairs with total energy near the maximum energy of a bremsstrahlung spectrum \( ^{63,64,65} \)
2. detection of \( p \pi^+ \pi^- \) for \( |t| > \sim 0.02 \text{ GeV}^2 \) using bubble \( ^{2,10,11,28} \) or streamer chambers, \( ^{66} \)
3. detection of the recoiling proton in a missing mass spectrometer. \( ^{67} \)

We first compare our data to the double-differential cross section, \( \frac{d^2 \sigma}{d\Omega dM} \), for dipion production in the forward direction obtained by the DESY-MIT \( ^{65} \) group using the first technique.

In order to derive \( \frac{d^2 \sigma}{d\Omega dM} \) in the forward direction we have fitted our data to the form \( B \exp(At) \) in the \(|t| \) interval 0.02 to 0.4 GeV\(^2 \) in 40 MeV intervals of \( \pi \pi \) mass. The quantity \( B \exp(At) \) expressed in \( \mu b/\text{sr MeV} \) is plotted in Figs. 23(a) (2.8 GeV) and (b) (4.7 GeV) together with the data of the DESY-MIT group \( ^{65} \) at 2.9 GeV and 4.7 GeV. From the figure it may be seen that the DESY-MIT data yield a cross section which is higher, by about a factor 1.4, than the data of this experiment at the peak of the \( \rho^0 \). It is noteworthy that the shape of the data from the two experiments is similar in the \( \rho^0 \) region.

Apart from uncertainties in the normalization of the DESY-MIT experiment, which are \( \sim 10\% \), two effects could be responsible for the discrepancy.

(a) The data of the DESY-MIT group may contain a contribution from dipion pairs produced inelastically.
(b) The exponential extrapolation of our data to the forward direction may yield an incorrect estimate of the forward cross section if the slope changes at small $|t|$.  

In order to illustrate the form of contamination that may occur in a counter experiment of the DESY-MIT type, we have selected $\pi^+\pi^-$ pairs from events other than $\gamma p \to p\pi^+\pi^-$ with the laboratory momentum, $Q$, of a $\pi^+\pi^-$ pair satisfying $|Q - Q|/Q < 0.18$, where $Q = E_{\gamma}^{\text{max}} / 1.15$. We have chosen these limits to approximate the acceptance of the DESY-MIT experiment. The mass spectra of pion pairs satisfying the criterion are shown in Fig. 24 (a), (b) for dipion transverse momentum squared $Q_T^2 < 0.05$ GeV$^2$. Inelastically produced $\rho^0$'s occur at small $Q_T^2$ at 4.7 GeV; they persist to some extent at higher $Q_T^2$. At 2.8 GeV there is no strong evidence for inelastic $\rho^0$ production at small $Q_T^2$. A non-resonant background is present at both energies. The distribution of $Q$ for elastic (i.e., from $\gamma p \to p\pi^+\pi^-$) and inelastic $\pi^+\pi^-$ pairs with $0.6 < M_{\pi\pi} < 0.9$ GeV is shown in Fig. 24 (c), (d). If we take our $E_{\gamma}$ spectrum to be a line spectrum with energy $E_{\gamma}^{\text{max}}$, we can estimate the background in the DESY-MIT experiment by assuming that the form of the $Q_{\text{inelastic}}$ distribution expressed as a function of $E_{\gamma}^{\text{max}} - Q$ is independent of $E_{\gamma}$ within the range of the DESY-MIT acceptance. We then weight the inelastic contributions with $1/E_{\gamma}$ (to approximate the bremsstrahlung spectrum of Ref. 65) and integrate over the acceptance region. The resulting background estimates are shown in Fig. 24 (e), (f); we see that the background is $\sim 12\%$ and is roughly independent of $Q_T^2$. This estimate will decrease slightly if differences in the decay angular distribution of elastic and inelastic dipion pairs are taken into account. We emphasize that the background estimate of Fig. 24 (e), (f) includes all inelastic dipion pairs within
the interval $0.6 < M_{\pi \pi} < 0.9$ GeV. Appropriate fits to the counter data may subtract out the inelastic nonresonant but not the inelastic $\rho^0$ contribution to the background.

From this we conclude that the forward $\rho^0$ cross section at 4.7 GeV measured by the DESY-MIT group\textsuperscript{65} could be overestimated by $\sim 5\%$ due to a background of inelastic $\rho^0$ production. A recent measurement at Cornell\textsuperscript{69} indicates that the inelastic contamination in their experiment\textsuperscript{64}, which has a similar acceptance to the DESY-MIT experiment, is $\sim 5\%$.

A quadratic extrapolation to the forward direction (i.e., using the form $e^{At + Bt^2}$) increases our values of $d^2 \sigma / d \Omega dM$ by about 12\% (cf Table XI); this together with an $\sim 10\%$ inelastic background (of which half is inelastic $\rho^0$) in the DESY-MIT data would reduce the discrepancy in $d^2 \sigma / d \Omega dM$ between this and the DESY-MIT experiment to about 15\%, a value which is close to the uncertainty of normalization of the DESY-MIT experiment.

We next compare $d\sigma / dt$ for $0.05 < |t| < 1$ GeV$^2$ with other experiments. In Fig. 25 we show our 4.7 GeV differential $\rho^0$ cross sections, determined by the parameterization method, together with similarly determined cross sections from the DESY bubble chamber\textsuperscript{11} ($4.5 < E_\gamma < 5.8$ GeV) and a SLAC counter experiment,\textsuperscript{67} ($E_\gamma \sim 6$ GeV). Within statistics the agreement between the three experiments is excellent. We remark that since the SLAC counter experiment detects the recoil proton in $\rho^0$ production there is no problem with contamination due to inelastic $\rho^0$ production. Our differential cross sections are also in agreement with those obtained using a positron annihilation beam.\textsuperscript{28}

The values obtained for the forward $\rho^0$ cross section in the SLAC counter experiment and ours differ due to the $t$-range fitted and the form of curve used to extrapolate to $t = 0$. Anderson et al.\textsuperscript{67} used the shape of the
experimental elastic π p scattering differential cross section and from a fit in the |t| interval 0.1 to 1.2 GeV² found dσ/dt|t=0 = 152 ± 15 µb/GeV². A straight line extrapolation of their data for |t| < 0.7 GeV² would actually fall below our value of 114 ± 6 µb/GeV²; quadratic extrapolations give results in agreement with ours when fits are made in the |t| - range 0.02 - 1.0 GeV².

In conclusion, the results of this experiment agree well with other experiments in the t interval 0.05 < |t| < 1 GeV². Our forward differential cross sections, dσ/dt|t=0, are lower than those of Anderson et al.⁶⁷ due only to the form of extrapolation used. The dipion forward cross section d²σ/dΩdM at 4.7 GeV of the DESY-MIT group⁶⁵ is higher than that obtained in this experiment and we have demonstrated that this is partly due to an ~ 10% inelastic background. The remaining discrepancy, if not due to normalization problems in the counter experiment, may result from our procedure for extrapolating to t = 0.

It must be emphasized that these conclusions are based upon comparing our parameterization cross section and an extrapolation of our raw data with other experiments. Due to differences in the methods of analysis⁷⁰ we have not compared our Söding model cross sections with those from other experiments.¹¹,⁶⁴,⁶⁵
6. Discussion of Cross Sections for $\rho^0$ Production

In Table XI we have given six dipion forward cross sections for each energy using three techniques and two forms of extrapolation. Total cross sections are also given for each technique; they are insensitive to the form of extrapolation used. We here consider the problem of which dipion cross section gives the best measure of the $\rho^0$ cross section.

Firstly we consider the three techniques used to determine a dipion cross section. A problem arises because both the Kramer-Quinn model and the Söding model are compatible with our data. These two models lead to different definitions of $\rho^0$: the Kramer-Quinn model suggests that all p-wave dipion pairs should be considered as $\rho^0$ so that $\Pi$ gives the cross section for s-channel helicity-conserving $\rho^0$ production and the parameterization cross section gives the total $\rho^0$ cross section. On the other hand, the Söding model suggests that there is a coherent p-wave background under the $\rho^0$ which should be subtracted out in order to determine a $\rho^0$ cross section. The two approaches lead to substantially different forward $\rho^0$ cross sections; since the Söding model gives the best quantitative fit to the data we are led to favor the Söding model cross sections, but we do not rule out the possibility that $\rho^0$ cross section should be determined from $\Pi$ or by the parameterization technique. More generally, our Söding model cross sections give the cross section for $\rho^0$ production when the $\rho^0$ cross section is defined as that obtained through the integration of a Breit-Wigner distribution which is normalized to the height of the dipion mass spectrum at the $\rho^0$ mass (with, of course, appropriate subtractions of $\Delta^{++}$ and "phase space"); to this extent the Söding model cross sections can be considered model independent.
We have used two fits \(e^{At} \) and \(e^{At} + Bt^2\) to obtain forward cross sections. Both these parameterizations of the differential cross section fit the data equally well and from Table XI it may be seen that \(B\) is zero within errors. However, differential cross sections are usually fitted with a \(B\) term (e.g., \(\pi p\) elastic scattering), so the forward \(\rho^0\) cross sections and errors obtained using the \(e^{At} + Bt^2\) fit may be more realistic than those obtained with a linear extrapolation.

D. \(\rho^0 - \omega\) Interference

The combined data of the 2.8 and 4.7 GeV exposures show a 2.5 SD effect in the \(\pi^+\pi^-\) mass spectrum that may be attributed to \(\rho^0 - \omega\) interference (see Fig. 26). Our analysis of \(\rho^0 - \omega\) interference has recently been published. Since the \(\omega \rightarrow 2\pi\) decay rate is small and the interference effect is symmetric about a smooth curve through the \(\rho^0\) mass spectrum, the effect of \(\rho - \omega\) interference on our \(\rho^0\) cross sections given above is negligible. In addition, fits using the parameterization technique with \(\rho^0 - \omega\) interference included, show that \(n(t)\) (see section IV-C1) is unaltered.

E. \(\Delta\) Production

1. Cross sections and decay distributions

In Fig. 10(b) we show the \(\pi^+p\) mass spectra for reaction \(\gamma p \rightarrow p\pi^+\pi^-\). At both energies a clear \(\Delta^{++}\) signal is found; some \(\Delta^0\) production may also be present. The shaded distributions are for events selected with \(|t_{\Delta}| < 0.4\) GeV\(^2\) (\(t_{\Delta}\) is the momentum transfer between the proton and the \(\Delta\)) and \(M_{\pi^+\pi^-} > 1.0\) GeV in order to remove most of the \(\rho^0\) reflection and to minimize other backgrounds.

The solid curves in Fig. 10 were obtained from the Söding model fit with an incoherent \(\Delta\) as described in Appendices A and B. As can be seen from
the figure this gives a reasonable fit to the mass spectrum in both the \( \Delta \) region and in the high \( \pi p \) mass region. We emphasize that in fitting the amount of \( \Delta^{++} \) we have chosen a shape for the \( \Delta \) which agrees with that expected from the \( (3,3)\pi N \) phase shift, \( \delta_{33} \). The matrix element for \( \Delta \) production, \( T_\Delta \), has the form

\[
\left| T_\Delta \right|^2 \sim \frac{M}{q(M)} \sin^2 \delta_{33} \sim \frac{1}{\Gamma(M)} \cdot \frac{M}{q(M)} \cdot \frac{(M_\Delta \Gamma(M))^2}{(M_\Delta^2 - M^2)^2 + (M_\Delta \Gamma(M))^2}
\]

(9)

where \( \Gamma(M) \) follows from \( \tan \delta_{33} = \frac{M_\Delta \Gamma(M)}{(M_\Delta^2 - M^2)} \), \( M_\Delta = 1.236 \) GeV, \( M \) is the \( \pi^+ p \) or \( \pi^- p \) mass, and \( q(M) \) is the momentum of the proton in the \( \pi p \) c.m.s.. The values of \( \delta_{33} \) have been taken from a phase shift analysis.\(^{71}\)

In Table XIV the total cross sections for production of \( \Delta^{++} \) and \( \Delta^0 \) (\( p\pi^- \) decay mode only) are given for the two energies. Figure 27 and Table XV show the differential cross sections \( d\sigma/dt \) for \( \Delta^{++} \) production obtained from an independent maximum likelihood fit as described above for each \( t_\Delta \)-interval. Corrections for \( \Delta^{++} \) production due to contamination from wide-angle electron-positron pair production and for scanning losses of events with short recoil protons (proton momenta < 0.14 GeV/c) were found to be negligible from a Monte-Carlo simulation.\(^{30}\) If the second part of Equation (9) is used together with a conventional parameterization for \( \Gamma(M) \),\(^{72}\) as was done by Boyarski et al.\(^{73}\), \( \Delta \) cross sections are found that are larger by \( \sim 20\% \) than those given here.

The \( \Delta^{++} \) angular distributions have been analyzed in terms of the \( \Delta \) spin density matrix in the Gottfried-Jackson frame. The \( z \) axis is taken as the direction of the incident proton in the \( \Delta \) rest frame; the \( y \) axis is defined as the normal to the production plane (\( \hat{y} \times \hat{x} \hat{\gamma}^- \)). The electric vector \( \hat{\gamma} \) of the photon makes an angle \( \phi \) with the production plane: \( \cos \phi = \hat{\gamma} \cdot (\hat{\gamma} \times \hat{\gamma}^-) \), \( \sin \phi = \hat{\gamma} \cdot \hat{\epsilon} \). The decay angles \( \theta \) and \( \phi \) are the polar and azimuthal angles of the outgoing
proton in the $\Delta$ rest system: $\cos \theta = \hat{p} \cdot \hat{2}$, $\cos \phi = \hat{r} \cdot (\hat{2} \times \hat{2})/|\hat{2} \times \hat{2}|$, $\sin \phi = -(\hat{r} \times \hat{2})$. The decay angular distribution is then given by:

$$W(\cos \theta, \phi, \rho) = \frac{3}{4\pi} \left[ \rho_{33}^0 \sin^2 \theta + \left( \frac{1}{2} - \rho_{33}^0 \right) \left( \frac{1}{3} + \cos^2 \theta \right) ight.$$

$$- \frac{2}{\sqrt{3}} \text{Re} \rho_{31}^0 \cos \phi \sin 2 \theta - \frac{2}{\sqrt{3}} \text{Re} \rho_{3-1}^0 \cos 2 \phi \sin^2 \theta$$

$$- \rho_Y \cos 2 \phi \left[ \rho_{33}^1 \sin^2 \theta + \rho_{11}^1 \left( \frac{1}{3} + \cos^2 \theta \right) \right]$$

$$- \frac{2}{\sqrt{3}} \text{Re} \rho_{31}^1 \cos \phi \sin 2 \theta - \frac{2}{\sqrt{3}} \text{Re} \rho_{3-1}^1 \cos 2 \phi \sin^2 \theta$$

$$- \rho_Y \sin 2 \phi \left[ \frac{2}{\sqrt{3}} \text{Im} \rho_{31}^2 \sin \phi \sin 2 \theta 
+ \frac{2}{\sqrt{3}} \text{Im} \rho_{3-1}^2 \sin 2 \phi \sin^2 \theta \right] \right]$$

(10)

where $\rho_Y$ is the degree of linear polarization.

We define the parity asymmetry, $\rho_\sigma$, in terms of the cross sections for natural and unnatural parity exchange in the $t$-channel, $\sigma^N$ and $\sigma^U$:

$$\rho_\sigma = \frac{\sigma^N - \sigma^U}{\sigma^N + \sigma^U}$$

(11)

Since a meson of spin zero is produced at the photon vertex, we can find $\rho_\sigma$ from the azimuthal distribution of the production normal with respect to the plane of polarization of the photon. At high energies we have:

$$W(\phi) = 1 - \rho_\sigma \cdot \rho_Y \cdot \cos 2 \phi$$

(12)

In terms of density matrix elements:

$$\rho_\sigma = \text{Tr} \rho^1 = 2(\rho_{33}^1 + \rho_{11}^1)$$

(13)

Counter experiments detecting the $\pi^-$ only measure the polarization asymmetry $A$: 

- 43 -
\[
A = \frac{\sigma_{\perp}}{\sigma_{\perp} + \sigma_{\parallel}} = P_{\sigma} \cdot P_{Y} \tag{14}
\]

To obtain the nine measurable density matrix parameters and \(P_{\sigma}\), events were selected with \(M_{p\pi^+} < 1.32\ \text{GeV}\) and the method of moments was used with the Eberhard-Pripstein procedure\(^{76}\) to remove the \(\rho^0\) reflection. Only events with \(-1.0 < \cos \theta_{H} < 0.3 < 0.7\) at \(2.8\ \text{GeV} < 4.7\ \text{GeV}\) were used, where \(\theta_{H}\) is the angle in the \(\Delta\) rest frame between the decay proton and the \(\Delta\) line of flight in the total c.m.s.. Figure 28 and Table XVI show the \(p_{ik}^\alpha\) and \(P_{\sigma}\) obtained this way. The values of \(P_{\sigma}\) averaged over \(|t| < 0.5\ \text{GeV}^2\) are given in Table XIV. It is clear that OPE alone (i.e., the Soding model) cannot explain the data since it would require \(P_{\sigma} = -1(\rho_{11}^1 = -1/2\) and all other \(p_{ik}^\alpha\) in Equation (10) equal to zero). Qualitatively the same result was obtained in an experiment done at low energy.\(^{77}\)

2. Comparison with theory

The values of \(P_{\sigma}\) show that \(\Delta^{++}\) production does not occur through one pion exchange alone. At lower energies it was found\(^{11}\) that the minimal gauge invariant extension of one pion exchange exchange (GIOPE) of Stichel and Scholz\(^{78}\) including absorption corrections in the final state\(^{79}\) gives a fair description of \(\Delta^{++}\) production for \(|t| < 0.3\ \text{GeV}^2\). At high energies and very small momentum transfers (\(|t| < 0.15\ \text{GeV}\)) it was observed that the GIOPE in the Born approximation reproduces well the differential cross section.\(^{73}\) Following the idea of vector dominance we calculated the predictions of GIOPE applying absorption corrections both in the initial and final state.\(^{80}\) This was done by multiplying the helicity amplitudes for spin \(J\) by the factor\(^{81}\)

\[
\left(1 - C_{\text{in}} \exp\left(-\frac{(J - \frac{1}{2})^2}{2A_{\text{in}}q_{\text{in}}^2}\right)\right)^{1/2} \left(1 - C_{\text{out}} \exp\left(-\frac{(J - \frac{1}{2})^2}{2A_{\text{out}}q_{\text{out}}^2}\right)\right)^{1/2},
\]
where \( q \) is the c.m.s. momentum, \( A \) the slope parameter, \( C \) the absorption parameter \( (C = \sigma_T/4\pi A, \sigma_T \) the total cross section for scattering of either the initial or final state particles) and the indices "in", "out" refer to the initial and final states respectively. The slope parameters were assumed to be the same as measured for Compton scattering and elastic \( \pi p \) scattering respectively, i.e. \( A_{in} = 6 \text{ GeV}^{-2}, A_{out} = 8 \text{ GeV}^{-2} \). For the absorption parameters \( C_{in}, C_{out} \) several sets of values between zero and unity were tried (see below). The finite width of the \( \Delta \) was taken into account by integrating over the \( \pi^+ p \) mass range using the \( (3, 3) \) elastic scattering cross section.

The solid curves in Fig. 27 show the predictions of GIOPE for 
\[
d\sigma/dt_\Delta (\gamma p \rightarrow \Delta^{++} \pi^-) \text{ for } C_{in} = C_{out} = C = 0.8.
\]
For comparison we also give the predictions for \( C=1 \) (dashed curves). The curves for \( C=1 \) agree approximately with the data for \( |t_\Delta| < 0.3 \text{ GeV}^2 \); at larger \( |t_\Delta| \) too much \( \Delta^{++} \) is predicted. It is interesting to note that, for \( |t_\Delta| > 0.02 \text{ GeV}^2 \), the OPE graph alone leads to approximately the same \( d\sigma/dt_\Delta \).

In Fig. 28 we compare the measured density matrix parameters and \( P_\sigma \) with the predictions of GIOPE. It can be seen that the diagrams necessary to give gauge invariance simulate some natural parity exchange contributions in the \( t \)-channel. Although there is agreement for \( |t_\Delta| \lesssim 0.1 \text{ GeV}^2 \) in an average sense, we cannot test the strong variations predicted by GIOPE for \( |t_\Delta| \lesssim 0.1 \text{ GeV}^2 \). For \( |t_\Delta| > 0.1 \text{ GeV}^2 \) some of the \( \rho_{ik}^\sigma \) and \( P_\sigma \) are not reproduced well.

Vector dominance (VDM) relates the reaction \( \gamma p \rightarrow \pi^- \Delta^{++} \) to the reactions \( \pi p \rightarrow \Delta V^0 \) where \( V^0 \) is \( \rho^0, \omega \) or \( \phi \). Gotsman \(^82\) has fitted the latter reactions to a sum of Regge exchange amplitudes in order to perform the line reversal needed for the comparison. With \( \gamma^2_p/4\pi = 0.5 \) (\( \gamma_p \) describes the \( \gamma-\rho \) coupling strength), his predictions for 5 GeV are in fair agreement \(^83\)
with our $d\sigma/dt$ for $|t| > 0.1 \text{ GeV}^2$. While the predictions for some of the $\rho_{ik}$ and for $P_{\sigma}$ (see dot-dashed curve in Fig. 28) are in qualitative agreement, the prediction $P_{33}^0 \approx 0$ is not supported by the data.

In conclusion, the density matrix parameters, the parity asymmetry, and the differential cross section, indicate the presence of processes other than OPE in $\Delta^{++}$ production. We are thus left with the result that whereas $\rho^0$ production in the $p\pi^+\pi^-$ channel can be explained well by the Söding model, $\Delta^{++}$ production cannot. There is not necessarily any conflict in this because there is little overlap between the $\rho^0$ and $\Delta^{++}$. The $\rho^0$ mass asymmetry is due to interference with $\pi^+\pi^-$ pairs corresponding mainly to higher $\pi p$ masses which are assumed to originate from OPE in the framework of the Söding model. However, the scarcity of events other than phase space like background outside the $\rho^0$ and $\Delta^{++}$ bands (see Figs. 8, 30) prevents us from testing this assumption by analyzing the angular distributions in this region.

F. Search for High Mass Vector Meson Production

The $\pi^+\pi^-$ mass distributions in the channel $\gamma p \rightarrow p\pi^+\pi^-$ have been examined for the production of higher mass vector mesons, in particular the vector mesons $\rho'$ and $\rho''$, with masses of $\sim 1.3$ and $1.7 \text{ GeV}$ predicted by the Veneziano model. We used the technique described in Appendix A, plus an additional Breit-Wigner distribution corresponding to the $\rho'$ or $\rho''$, to fit the Dalitz plot. The fitted cross section for the vector meson is approximately proportional to $\Gamma/R$ where $\Gamma$ is the width of the resonance and $R$ is the fraction of decay to a dipion state. With $\Gamma = 200 \text{ MeV}$, $R = 1$, and the masses given above, we find upper limits (1 s.d.) at $4.7 \text{ GeV}$ of $0.5 \mu b$ and $0.3 \mu b$ for the $\rho'$ and $\rho''$ respectively.
G. Summary of the Channel $\gamma p \rightarrow p\pi^+\pi^-$

The channel has been shown to be dominated by $\rho^0$ and $\Delta^{++}$ production. We summarize the characteristics of $\rho^0$ production in (1)-(4) and of $\Delta^{++}$ production in (5).

1. Dipion mass distribution

In common with other photoproduction experiments we find that the $\rho^0$ produced in the channel $\gamma p \rightarrow p\pi^+\pi^-$ is shifted to lower masses than found in $\pi p$ interactions and that the $\rho^0$ shape is skewed with respect to a p-wave Breit-Wigner distribution. We have shown, in addition, that the $\rho^0$ mass shape changes as a function of the momentum transfer.

2. Dipion angular distribution

The dipion angular distribution was studied by the method of moments and by a density matrix analysis.

We conclude:

a. the dipion pairs in the $\rho^0$ region are in a predominantly p-wave state and it is the p-wave part of the mass spectrum that shows the skewing,

b. p-wave dipion production occurs predominantly through natural parity exchange in the t-channel,

c. the p-wave pion pairs are produced by a mechanism that, within errors, conserves s-channel c.m.s. helicity at the $\gamma\pi\pi$ vertex for $|t| < 0.4 \text{ GeV}^2$.

3. Comparison of dipion production with models

We find that a modified Söding model describes well:

a. The shape of the dipion mass spectrum and its change with momentum transfer,

b. the variation of the dipion density matrix elements with dipion mass,

c. the moments corresponding to dipion states with spin greater than
unity.

Other models do not describe well at least one of the above features of the data.

4. Dipion cross sections

By using the dipion angular distribution and the dipion mass spectrum we have determined two dipion cross sections, namely, the s-channel helicity-conserving p-wave cross section, \( \Pi \), and the parameterization cross section. We emphasize that neither \( \Pi \) nor the parameterization cross section are necessarily rho cross sections. Both \( \Pi \) and the parameterization cross sections agree well with other experiments for \(|t| > 0.05 \text{ GeV}^2\). The extrapolation of our cross sections to \( t = 0 \) is compatible with other experiments. Discrepancies in the published forward cross sections can be understood as the result of inelastic backgrounds in other experiments and/or the extrapolation procedures used.

We deduce a rho cross section using the Söding model. Our Söding model analysis shows that the rho cross section is uncertain to \( \sim 20\% \), due to theoretical uncertainties in the model and lack of knowledge of the rho mass and width.

5. \( \Delta^{++} \) production

A density matrix analysis shows that the \( \Delta^{++} \) is produced by a mixture of natural and unnatural parity exchange in the t-channel. Neither the vector dominance model of Gotsman\(^{82}\) nor the modified GIOPE model describes both the \( \Delta^{++} \) differential cross sections and density matrix elements.
ACKNOWLEDGEMENTS

We wish to thank the SLAC operations crew of the accelerator and R. Watt and the 82" bubble chamber operation group. We thank P. Klein and W. Graves for help in the early stages of the experiment. We acknowledge the diligent work of the scanners at SLAC and Berkeley and in particular the help in data reduction by D. Blohm, K. Eymann, W. Hendricks, M. Tartar and A. Wang. We thank Professors D. Yennie, F. Gilman, J. Pumplin and Dr. A. Schwimmer for many useful discussions and suggestions.
APPENDIX A

Fitting Procedure for the Parameterization Cross Sections

and the \( \rho^0 \) Density Matrix Elements

The probability, \( dP \), for producing a given event of the reaction

\[ \gamma p \rightarrow p \pi^+ \pi^- \text{ with } \pi\pi \text{ mass, } M_{\pi\pi}, \pi^+ p \text{ mass, } M_{\pi^+ p} \text{ and with } \pi^+ \pi^- \text{ angles } \theta, \phi \]

and \( \phi \) (defined in footnote 36) was taken to be

\[ dP = |M|^2 \, d \text{ (phase space)} \]

where

\[ |M|^2 = a_\rho \, BW_\rho \left( M_{\pi\pi} \right) \left( M_\rho / M_{\pi\pi} \right)^n(t_\rho) \, W(\theta, \phi, \Phi) \, (t_\rho / t_\rho^0) / N_\rho \]

\[ + a_\Delta \, BW_\Delta \left( M_{\pi^+ p} \right) \frac{F(t_\Delta)}{N_\Delta} + a_{ps} / N_{ps}. \quad (A.1) \]

Here, \( a_\rho, a_\Delta \) and \( a_{ps} \) are the fractions of \( \rho, \Delta^{++} \) and phase space respectively \((a_\rho + a_\Delta + a_{ps} = 1)\). \( BW_\rho \) is a relativistic Breit-Wigner distribution with an energy dependent width suggested by Jackson\(^72\)

\[ BW_\rho \ (M_{\pi\pi}) = \left( M_{\pi\pi} / q(M_{\pi\pi}) \right) \frac{M_\rho \ \Gamma(M_{\pi\pi})}{(M_{\pi\pi}^2 - M_\rho^2)^2 + M_\rho^2 \ \Gamma^2(M_{\pi\pi})} \quad (A.2) \]

where \( q(M_{\pi\pi}) \) is the momentum of a pion in the dipion rest frame and

\[ \Gamma(M_{\pi\pi}) = \Gamma_\rho \left[ q(M_{\pi\pi}) / q(M_\rho) \right]^3 \frac{2}{\{ 1 + (q(M_{\pi\pi}) / q(M_\rho))^2 \}} \quad (A.3) \]

The \( \Delta^{++} \) shape used is

\[ BW_\Delta \ (M_{\pi^+ p}) = \left( M_{\pi^+ p} / q(M_{\pi^+ p}) \right) \sin^2 \delta_{33} / \left( M_\Delta \ \Gamma(M_{\pi^+ p}) \right) \quad (A.4) \]
with $\delta_{33}$ taken from a phase shift analysis $^{71}$ and

$$\Gamma(M_{\pi^+p}) = \tan \delta_{33} \left( M^2 - M^2_{\pi^+p} \right) / M_\Delta,$$

with $M_\Delta = 1.236$ GeV, and $q(M_{\pi^+p})$ is the momentum of the proton in the $\pi^+p$ rest frame. Here $W(\theta, \phi, \rho)$ describes the $\rho$ decay angular distribution for the appropriate frame and is given in Eq. (2) of section IV-B3; $t_\rho$ is the square of the momentum transfer from $\gamma$ to $\rho$ and $A_\rho$ is the slope of the momentum transfer distribution of the $\rho$; $F(t_\Delta)$ is a description of our observed momentum transfer distribution of the $\Delta$. The decay of the $\Delta^{++}$ is nearly isotropic and it was therefore not necessary to include a detailed decay distribution. $N_\rho$, $N_\Delta$ and $N_{ps}$ are normalization factors which ensure that the $\rho$, $\Delta$ and phase space terms integrate to unity over the Dalitz plot.

The likelihood function was written as $\sum lndP_i$ and was maximized in the fits by varying parameters in the combinations appropriate to the fits as discussed below. For the maximization we used the programs MURTLEBERT and OPTIME.$^{85}$

1. Parameterization Cross Section Fits

In these fits to the Dalitz plot the $\pi^+\pi^-$ angular distribution, $W(\theta, \phi, \rho)$, was set equal to $\frac{3}{4} \sin^2 \theta_H$ and $M_\rho$, $\Gamma_\rho$ and $A_\rho$ were determined from an overall fit in the region $0.02 < |t_\rho| < 0.4 \text{ GeV}^2$ with an approximate linear $n(t)$ dependence (see Fig. 20 and Ref. 17). With $M_\rho$, $\Gamma_\rho$, and $A_\rho$ fixed at these values, the quantities $-a_\rho$, $a_\Delta$ and the final value of $n(t)$ were fitted for different $t_\rho$ intervals.

2. $\rho$ Density Matrix Element Fits

In these fits using all the independent variables except $t$, $W(\theta, \phi, \rho)$ was expressed in terms of the nine independent density matrix elements (Eq. (2)); $M_\rho$, $\Gamma_\rho$, $A_\rho$, $n(t)$, $a_\rho$ and $a_\Delta$ were set at the values determined above and the nine density matrix elements were fitted. No constraints were applied to the density matrix elements.
APPENDIX B

The Söding Model

We have calculated the predictions of the Söding model\textsuperscript{49} using a modified version of a computer program written by P. Söding. The matrix element used to describe the reaction $\gamma p \rightarrow p\pi^+\pi^-$ is the sum of helicity conserving $\rho$ production (diagram (a) of Fig. 29), two Drell diagrams (Fig. 29 (b)), a rescattering term (Fig. 29 (c)), and incoherently, $\Delta^{++}$ production and a phase space term.

A $\rho$ production amplitude may be defined in one of two ways, namely:

1. as diagram (a) or
2. as the sum of diagrams (a) and (c) in Fig. 29.

We choose the first definition since, for $\Gamma_\rho \rightarrow 0$, (i.e. the limit of a stable $\rho^0$) diagram (c), which depends on $\Gamma_\rho^2$, vanishes with respect to diagram (a). This definition is also in keeping with the vector dominance picture of photon interactions (see the discussion of Bauer\textsuperscript{51}), and with the intuitive view that (c) is a correction to the Drell terms (b). The analysis presented in the text uses definition (1).

At the end of this Appendix we discuss briefly an argument for, and the results of using, definition (2).

We write the matrix element as

$$|M|^2 = a_s |F_\rho \hat{\epsilon}_\rho \cdot \vec{q}(M_{\pi\pi}) + Y(F_{\pi^-} + F_{\pi^+})|^2 / N_s$$

$$+ a_\Delta \, BW_\Delta \, F_\Delta (t_\Delta) / N_\Delta + (1 - a_s - a_\Delta) / N_{ps},$$

(B.1)

where $a_s$, $a_\Delta$ are the fractions of dipion production described by the Söding model and $\Delta^{++}$ production, respectively; $N_s$, $N_\Delta$ and $N_{ps}$ normalize the three terms to unity when integrated over phase space. The relative amounts of the $\rho^0$ and Drell terms are given by $Y$. 

- 52 -
\( F_\rho \) is the \( \rho \) amplitude with

\[
F_\rho = i e^{\frac{A_\rho t}{2}} \left( \sigma_\rho A_\rho e^{-\frac{A_\rho t_{\text{min}}}{2}} \right) E_{\text{Ems}} k_{\text{Ems}} / (M_\rho^2 - M_{\pi\pi}^2 - i M_\rho \Gamma) \tag{B.2}
\]

where \( A_\rho \) is the slope of the exponential momentum transfer, \( t \), distribution to the \( \rho \); \( M_\rho \) is the \( \rho \) mass; \( \Gamma \) is the \( \rho \) width with

\[
\Gamma = \Gamma_\rho \left( q(M_{\pi\pi}) / q(M_\rho) \right)^3 \frac{M_\rho}{M_{\pi\pi}} \tag{B.3}
\]

and \( q(M_{\pi\pi}), q(M_\rho) \) are the pion momenta in the \( \pi\pi \) rest frame for \( \pi\pi \) masses, \( M_{\pi\pi}, M_\rho \) respectively. The \( \rho^0 \) production cross section, \( \sigma_\rho \), was set to a nominal value (15 \( \mu b \)); \( t_{\text{min}} \) is the minimum momentum transfer necessary to produce the \( \rho^0 \). \( E_{\text{Ems}} \) and \( k_{\text{Ems}} \) are the total energy and the \( \gamma \) momentum in the \( \gamma p \) c.m.s.

Assuming s-channel helicity conservation for \( \rho^0 \) production, \( \hat{\epsilon}_\rho \) is calculated by rotating \( \hat{\epsilon}_\gamma \), the photon polarization vector in the c.m.s., through the \( \rho^0 \) c.m.s. production angle around the production normal.

For the Drell amplitudes we use

\[
F_{\pi^\pm} = \mp \left( \hat{\epsilon}_\gamma \cdot \hat{q}_{\pi^\pm} \right) T(\pi^\pm p) G(t_{\pi^\pm}) (m_\pi^2 - t_{\pi^\pm}) \tag{B.4}
\]

where \( t_{\pi^\pm} \) is the square of the momentum transfer between the photon and \( \pi^\pm \);

\( q_{\pi^\pm} \) is the momentum of the \( \pi^\pm \) in the \( \gamma p \) c.m.s. and \( G(t_{\pi^\pm}) \) is the form factor for off-shell \( \pi^\pm p \) scattering. We used the form factor of Ferrari-Selleri\(^{52}\)

\[
G(t_{\pi^\pm}) = 1 / \left( 1 + \frac{m_\pi^2 - t_{\pi^\pm}}{65 m_\pi^2} \right) \tag{B.5}
\]

Because of the Ward identity there should be no form-factor for the \( \gamma \pi \pi \) vertex.\(^{86}\)
With the form factor $G(t_{\pi^\pm})$ factored out, the off-shell elastic $\pi p$ scattering amplitude is set equal to the on-shell $\pi p$ scattering amplitude:

$$T_1(\pi p) = \sum_{\ell=0}^{3} [ (\ell+1) A_{\ell}^+ + \ell A_{\ell}^- ] P_{\ell}(\cos \theta) M_{\pi p}$$

$$T_2(\pi p) = \sum_{\ell=0}^{3} \left[ \sin \theta (A_{\ell}^+ - A_{\ell}^-) \frac{d}{d(\cos \theta)} P_{\ell}(\cos \theta) \right] M_{\pi p},$$

where $T_1, T_2$ are the non-spin-flip and spin-flip amplitudes respectively; $\theta$ is the $\pi p$ center of mass scattering angle, $M_{\pi p}$ is the $\pi p$ mass and $P_{\ell}(\cos \theta)$ are the Legendre polynomials. The elastic $\pi p$ partial wave amplitudes which are defined, in the usual notation, by $^8^7$

$$A_{\ell}^\pm = (\eta_{\ell}^\pm e^{2i\delta_{\ell}^\pm} - 1)/2i k_{\pi p},$$

where $k_{\pi p}$ is the $\pi$ momentum in the $\pi p$ rest frame, correspond to $J = \ell \pm 1/2$. For $\pi^- p$ the appropriate isospin sum is used for the $A_{\ell}^\pm$. For $\pi p$ masses greater than 1.74 GeV we take $T(\pi^\pm p)$ to be purely imaginary with an exponential $t$ dependence.

The $T_1$ term is multiplied by $(M_{\rho}^2 - M_{\pi}^2)/(M_{\rho}^2 - M_{\pi}^2 - i M_{\rho} \Gamma_{\rho})$ which is an approximation to the rescattering correction $^5^0$ corresponding to the inclusion of diagram (c) of Fig. 29. The use of the rescattering correction in this form is justified by the fact that the Drell term produces predominantly $p$-wave $\pi\pi$ pairs. $^5^0$

In order to test this approximation we have calculated the model both with and without the rescattering correction and have found that the correction does not significantly alter the predicted form of the dipion moments (in particular, $Y_{44}^0$) or the density matrix elements. The spin flip terms $T_2$ are assumed not to interfere with the $\rho^0$ so no rescattering correction was used on them; the $T_2$
terms were added incoherently to the $\rho^0$ and non spin flip Drell terms. This is an approximation to the fact that a helicity conserving $\rho^0$ amplitude does not interfere with the helicity-flip Drell amplitude.

The remaining terms in (B.1), corresponding to incoherent $\Delta^{++}$ and phase space, are described in Appendix A. In fitting the model the parameters $a_s$, $Y$, $a_\Delta$, $M_\rho$ and $\Gamma_\rho$ were varied as described in Section IV-C2.

The relative importance, and $t$ dependence, of the terms in the Söding amplitude is illustrated in Fig. 30. For this figure we used the Ferrari-Selleri form factor, (B.5), for $G(t_{\pi\pm})$.

Below we examine the sensitivity of the model to (a) the form factor in the Drell term, (b) the coherence of the $\Delta^{++}$ production amplitude, (c) the phase shifts, and (d) the phase of the rho production amplitude.

(a) We have tried the Ferrari-Selleri\textsuperscript{52} and Benecke-Dürr\textsuperscript{53} form factors and a constant for $G(t_{\pi\pm})$. Table XVI shows that the $\rho^0$ mass and width, the $\rho^0$ forward cross section and $A_\rho$ do not depend significantly on the form factor.

(b) The results presented in this paper are calculated with $\eta_{33} = 1.0$, $\delta_{33} = 0.0$ in $T(\pi^\pm)$ (i.e. no $\Delta$ in the Drell term) and the $\Delta^{++}$ term is added incoherently. We have also fitted the model with the $\Delta^{++}$ as predicted by the Drell amplitude plus an incoherent $\Delta^{++}$ and have found that all fitted values for the rho agree within one standard deviation.

(c) To check the importance of the accuracy of the phase shifts we have made the approximation $T_{1,2} = i \left| T_{1,2} \right|$ and have refitted the model. The results changed by less than one standard deviation.

(d) When $F_\rho$ is multiplied by $e^{-0.2i}$ ($\sim 20\%$ real part) the results are unchanged to within one standard deviation.
We conclude that our results are insensitive to a variation of the form of the Drell term within the limits allowed for by changes in the form factor, the coherence of $\Delta^{++}$ production or changes in phases. However, corrections to make the model gauge invariant could change the Drell term beyond these limits. 86

We now consider the calculation of the $\rho^0$ cross section when the $\rho^0$ is defined as the sum of diagrams (a) and (c) of Fig. 29. The physical idea behind this separation 88 is to define the $\rho^0$ amplitude as those parts of the amplitudes of Fig. 29 which vary rapidly with $M_{\pi\pi}$ in the region of the $\rho^0$ and to define as background that part which is smooth in the neighbourhood of $M_{\rho}$. Clearly the fitting procedure is unchanged and, to the extent that the Drell term, $D$, is imaginary, the $\rho^0$ cross section defined above is increased by a term proportional to $D^2 \sin^2 \delta$ where $\delta$ is the $\ell = 1, I = 1, \pi\pi$ phase shift. We obtain values for the $\rho$ cross section of $20.4 \pm 1 < 16.9 \pm 0.7 \mu$b at $2.8 < 4.7 > \text{GeV}$. The $\rho^0$ forward cross section increased to $109 \pm 6 < 102 \pm 6 \mu$b/GeV$^2$ at $2.8 < 4.7 > \text{GeV}$ which are 5-10% higher than the values in Table XI. The slope of the $\rho^0$ momentum transfer distribution is increased by about one standard deviation at both energies.
APPENDIX C

Helicity Amplitudes and Density Matrices of Photoproduced $\rho^0$ Mesons

In this Appendix we present the relation between the density matrices $\rho^\alpha_{ik}$ measured in this experiment and the helicity amplitudes describing $\rho^0$ photoproduction. (We use the notation of Ref. 35).

We write the helicity amplitudes, which are functions of $s$ and $t$, as

$$T_{\lambda_\rho, \lambda_{N'}, \lambda_y, \lambda_N},$$

where $\lambda_\rho$, $\lambda_y$, $\lambda_{N'}$, $\lambda_N$ are $\rho$ meson, photon, final and initial proton helicities.

Parity conservation gives the following relation between helicity amplitudes:

$$T_{\lambda_\rho, \lambda_{N'}, \lambda_y, \lambda_N} = (-1)^{(\lambda_\rho - \lambda_y) - (\lambda_{N'} - \lambda_N)} T_{-\lambda_\rho, -\lambda_{N'}, -\lambda_y, -\lambda_N},$$

consequently:

$$\sum_{\lambda_{N'} \lambda_N} \left\{ T_{\lambda_\rho, \lambda_{N'}, \lambda_y, \lambda_N} T^*_{\lambda_\rho, \lambda_{N'}, \lambda_y, \lambda_N} \right\} =$$

$$= (-1)^{(\lambda_\rho - \lambda_y) - (\lambda_{N'} - \lambda_N)} \sum_{\lambda_{N'} \lambda_N} \left\{ T_{-\lambda_\rho, \lambda_{N'}, -\lambda_y, \lambda_N} T^*_{-\lambda_\rho, \lambda_{N'}, -\lambda_y, \lambda_N} \right\}. \quad (C.1)$$

If only natural ($P = (-1)^J$) or only unnatural parity ($P = -(-1)^J$) exchanges contribute in the $t$-channel, we have to leading order in the energy of the incoming photon the
additional symmetry

\begin{equation}
T_{\lambda \rho \lambda_{N'}', \lambda_{N}, \lambda_{N}} = \pm (-1)^{\lambda_{\rho} - \lambda_{\gamma}} T^{*}_{\lambda \rho \lambda_{N'}, -\lambda_{\gamma} \lambda_{N}}
\end{equation}

where the upper (lower) sign applies to natural (unnatural) parity exchanges.

We define the density matrix elements by

\begin{align*}
\rho^{0}_{ik} &= \frac{1}{A} \sum_{\lambda_{N}, \lambda_{N'}} T_{\lambda \rho \lambda_{N}, \lambda_{N} \lambda_{N}} T^{*}_{\lambda \rho \lambda_{N'}, \lambda_{N}} \\
\rho^{1}_{ik} &= \frac{1}{A} \sum_{\lambda_{N}, \lambda_{N'}} T_{\lambda \rho \lambda_{N}, -\lambda_{\gamma} \lambda_{N}} T^{*}_{\lambda \rho \lambda_{N'}, \lambda_{N} \lambda_{N}} \\
\rho^{2}_{ik} &= \frac{i}{A} \sum_{\lambda_{N}, \lambda_{N'}} \lambda_{\gamma} T_{\lambda \rho \lambda_{N}, -\lambda_{\gamma} \lambda_{N}} T^{*}_{\lambda \rho \lambda_{N'}, \lambda_{N} \lambda_{N}} \\
\rho^{3}_{ik} &= \frac{1}{A} \sum_{\lambda_{N}, \lambda_{N'}} \lambda_{\gamma} T_{\lambda \rho \lambda_{N}, \lambda_{N} \lambda_{N}} T^{*}_{\lambda \rho \lambda_{N'}, \lambda_{N} \lambda_{N}}
\end{align*}

(C. 3)

with

\begin{equation}
A = \sum_{\lambda_{N}, \lambda_{N'}} T_{\lambda \rho \lambda_{N}, \lambda_{N} \lambda_{N}} T^{*}_{\lambda \rho \lambda_{N'}, \lambda_{N} \lambda_{N}}
\end{equation}

where $\rho_{ik}$ stands for $\rho_{\lambda \rho \lambda_{N}}^{i \rho_{k}}$.

If we use linearly polarized photons $\rho^{0}$, $\rho^{1}$ and $\rho^{2}$ can be measured; for circularly polarized photons $\rho^{0}$ and $\rho^{3}$ are measureable.

Using (C. 1), and with an implied summation over nucleon spins, we obtain
the following expressions for the density matrix elements in terms of helicity amplitudes $T_{\lambda\rho\lambda\gamma}$.

$$\rho_{00}^{0} = \frac{1}{A} (T_{0+} T_{0+}^{*} + T_{0-} T_{0-}^{*})$$

$$\rho_{11}^{0} = \frac{1}{A} (T_{++} T_{++}^{*} + T_{+-} T_{+-}^{*})$$

$$\text{Re} \rho_{10}^{0} = \frac{1}{A} \text{Re} (T_{++} T_{0+}^{*} + T_{-+} T_{0-}^{*})$$

$$\rho_{1-1}^{0} = \frac{1}{A} (T_{++} T_{++}^{*} + T_{+-} T_{+-}^{*})$$

$$\rho_{00}^{1} = \frac{1}{A} (T_{0+} T_{0-}^{*} + T_{0-} T_{0+}^{*}) = \frac{1}{A} \cdot 2 \text{Re} (T_{0+} T_{0-}^{*}) \quad (C.4)$$

$$\rho_{11}^{1} = \frac{1}{A} (T_{++} T_{++}^{*} + T_{+-} T_{+-}^{*}) = \frac{1}{A} \cdot 2 \text{Re} (T_{++} T_{++}^{*})$$

$$\text{Re} \rho_{10}^{1} = \frac{1}{A} \text{Re} (T_{++} T_{0+}^{*} + T_{-+} T_{0-}^{*})$$

$$\rho_{1-1}^{1} = \frac{1}{A} (T_{++} T_{++}^{*} + T_{+-} T_{+-}^{*})$$

$$\text{Im} \rho_{10}^{2} = \frac{1}{A} \text{Re} (T_{+-} T_{0+}^{*} - T_{++} T_{0-}^{*})$$

$$\text{Im} \rho_{1-1}^{2} = \frac{1}{A} (T_{+-} T_{++}^{*} - T_{+-} T_{++}^{*})$$

$$\text{Im} \rho_{10}^{3} = \frac{1}{A} \text{Im} (T_{++} T_{0+}^{*} - T_{--} T_{0-}^{*})$$

$$\text{Im} \rho_{1-1}^{3} = -\frac{1}{A} (T_{++} T_{--}^{*} - T_{+-} T_{--}^{*})$$

- 59 -
From the 11 independent density matrix elements ($\rho_{00}^O + 2\rho_{11}^O = 1$) and the cross section $\left( \frac{d\sigma}{d\Omega} = \left( \frac{2\pi}{E} \right)^2 \cdot \frac{A}{\gamma_{\text{CMS}}} \right)$ we get 10 bilinear combinations of helicity amplitudes:

\[
T_{++} T^*_{++} + T_{+-} T^*_{+-} = A \cdot \rho_{11}^O = T_{--} T^*_{--} + T_{-+} T^*_{-+}
\]

\[ (C.5) \]

\[
T_{0+} T^*_{0+} + T_{0-} T^*_{0-} = A \cdot \rho_{00}^O
\]

\[ (C.6) \]

\[
\text{Re} (T_{++} T^*_{+-}) = \frac{A}{2} \cdot \rho_{11}^1 = \text{Re} (T_{--} T^*_{-+})
\]

\[ (C.7) \]

\[
\text{Re} (T_{0+} T^*_{0-}) = \frac{A}{2} \rho_{00}^1 = \text{Re} (T_{0-} T^*_{0+})
\]

\[ (C.8) \]

\[
T_{++} T^*_{--} = \frac{A}{2} (\rho_{11}^1 - \text{Im} \rho_{11}^2) = T_{--} T^*_{++}
\]

\[ (C.9) \]

\[
T_{-+} T^*_{++} = \frac{A}{2} (\rho_{11}^1 + \text{Im} \rho_{11}^2) = T_{++} T^*_{-+}
\]

\[ (C.10) \]

\[
\text{Re} (T_{++} T^*_{0-}) = \frac{A}{2} (\text{Re} \rho_{10}^1 - \text{Im} \rho_{10}^2) = \text{Re} (T_{--} T^*_{0+})
\]

\[ (C.11) \]

\[
\text{Re} (T_{--} T^*_{0+}) = \frac{A}{2} (\text{Re} \rho_{10}^1 + \text{Im} \rho_{10}^2) = \text{Re} (T_{++} T^*_{0-})
\]

\[ (C.12) \]

\[
T_{++} T^*_{--} = \frac{A}{2} (\rho_{11}^O + i \text{Im} \rho_{11}^3) = T_{--} T^*_{++}
\]

\[ (C.13) \]

\[
T_{-+} T^*_{++} = \frac{A}{2} (\rho_{11}^O - i \text{Im} \rho_{11}^3) = T_{++} T^*_{-+}
\]

\[ (C.14) \]

A derived quantity is the parity asymmetry $P_\sigma$

\[ P_\sigma = 2 \rho_{11}^1 - \rho_{00}^1. \]

When $P_\sigma = \pm 1$ we get the following additional relation (inserting helicity amplitudes in $2 \rho_{11}^1 - \rho_{00}^1 = \pm 1$)

- 60 -
For $P_\sigma = \pm 1$ we have therefore:

\[
\left| T_{++} \mp T_{--} \right|^2 + \left| T_{+-} \mp T_{-+} \right|^2 + \left| T_{0+} \mp T_{0-} \right|^2 = 0
\]

This is the t-channel parity relation (C.2).

Some counter experiments measure the quantity:

\[
\sum = \frac{\rho_{1+}^1 \rho_{1-1}^1}{\rho_{11}^0 + \rho_{1-1}^0}
\]

which is not related unambiguously to natural and unnatural parity exchange. We get from $\sum = \pm 1$:

\[
(T_{++} \mp T_{+-}) (T_{-+}^* \mp T_{+--}) + (T_{+-} \mp T_{-+}) (T_{+--}^* \mp T_{-+}^*) = 0
\]

For pure natural (unnatural) parity exchange $\sum$ is $\pm 1$, but this would also happen for $T_{++} = \pm T_{+-}$ which has no relation to t-channel exchanges. From $\sum = \pm 1$ the parity of the t-channel exchange can be deduced only when either the non flip or the double flip amplitudes are zero.

A measurement of the angular distribution $W(\Phi)$ of the production plane (i.e. of the azimuthal distribution of the outgoing proton) with respect to the photon polarization vector gives:

\[
W(\Phi) = 1 - \cos 2 \Phi \cdot \text{Tr} \rho^1
\]
The quantity

\[ \text{Tr } \rho^1 = 2 \rho_{11}^1 + \rho_{00}^1 = \frac{1}{A} \left( \text{Re} (T_{0+}^0 T_{0-}^0) + 2 \text{Re} (T_{++}^+ T_{+-}^-) \right) \]

has no direct relation to the parity of the t-channel exchange. For helicity conservation \( \text{Tr } \rho^1 = 0 \) and \( W(\Phi) \) must be isotropic.

**Experimental Results**

In our experiment with linearly polarized photons we find:

\[
\begin{align*}
\rho_0 &\approx +1.0 \\
\rho_{11}^0 &\approx 0.5 \\
\rho_{1-1}^1 &\approx 0.5 \\
\text{Im } \rho_{1-1}^2 &\approx -0.5 \\
\end{align*}
\]

all other measurable elements are \( \approx \) zero

a) from (C.6) we conclude that helicity flips \( \lambda_\gamma = \pm 1 \) to \( \lambda_\rho = 0 \) vanish,

b) from (C.15) and (C.10) we conclude that helicity flips \( \lambda_\gamma = \pm 1 \) to \( \lambda_\rho = \mp 1 \) vanish,

c) from (C.15) we find \( T_{++}^+ = T_{--}^- \).

Point a) was known from unpolarized experiments. We have established b) and c) by using linearly polarized photons and by measuring the full angular distribution. Points a), b), c) together establish helicity conservation at the \( \gamma \rho \) vertex.

In the forward direction \( T_{+-}, T_{-+} \) go to zero \( 90^\circ \) because angular momentum conservation does not allow \( |\Delta \lambda| = 2 \). If these double flip amplitudes were large, a dip in the forward \( \rho^0 \) cross section would be expected. From an experiment using unpolarized photons which found no dip in the differential cross section at small \( t \), and a vanishing \( \rho_{00}^0 \), it could be concluded that helicity flip terms are small in the forward direction, but nothing could be deduced about the parity of the exchanged particle.

Programming Note - P-126 (1968), Lawrence Radiation Laboratory, Berkeley, unpublished.

20. This correction, which was not applied in our earlier publications, was determined by a careful rescan of part of our 4.7 GeV film. The corrections to $d\sigma/dt(\gamma p \rightarrow p\pi^+\pi^-)$ at 4.7 GeV are $15 \pm 6\%$, $5 \pm 4\%$, $5 \pm 5\%$ for the $|t|$ intervals $0.02-0.05 \text{ GeV}^2$, $0.05-0.075 \text{ GeV}^2$, $0.075-0.1 \text{ GeV}^2$, respectively.

24. We have checked the $pK^+K^-$ and $pK^+\pi^+\pi^-$ samples for possible contamination. The shape and position of the $E_\gamma$ and $\chi^2$ distributions are as expected for 3C fits, with $100\% < 90\%$ of the events inside the $E_\gamma$ limits $2.4 - 3.3 \text{ GeV} < 4.1 - 5.3 \text{ GeV}$. For $pK^+K^-$ fits simulated by $p\pi^+\pi^-\pi^0$ or $n\pi^+\pi^-\pi^-$ events one expects a flat $\chi^2$ distribution and energies below the $E_\gamma$ limits, which is in contrast to our observation. From this and Monte Carlo studies we estimate the contamination to be less than $5\% < 10\%$ at $2.8 < 4.7$ GeV.
This uncertainty is included in the errors of the cross sections.

25. Four of the nine events fitting $\gamma p \rightarrow p p \bar{p}$ had two baryon tracks which could be identified by ionization. All 9 events had fitted photon energies in the range $4.2 < E_\gamma < 5.0$ GeV and kinematic $\chi^2 < 8.0$ with an average $\chi^2$ of 3.2. These are the values expected for real events $\gamma p \rightarrow p p \bar{p}$ giving a 3C fit. For background events simulating this channel smaller $E_\gamma$ and larger $\chi^2$ would be expected. We therefore conclude that our sample contains no sizeable background contamination.

27. The cross sections at $E_\gamma = 1.44$ GeV were obtained from a small film sample taken in conjunction with the 2.8 and 4.7 exposures. A total cross section measurement at 1.44 GeV has been reported in Ref. 1. We use the same event sample and corrections as described in this reference.

31. A comparison of the channels $\gamma p \rightarrow n \pi^+ \pi^+ \pi^-$ and $\gamma p \rightarrow p \pi^+ \pi^+ \pi^-$ is made in Ref. 15. (See also G. Alexander et al., Phys. Rev. Letters 26, 340 (1971).

32. Cross sections for the channel $\gamma p \rightarrow p \pi^+ \pi^-$ are corrected for the region
|t| < 0.02 GeV$^2$ and for the loss of events with |t| > 0.02 GeV$^2$. These corrections are not applied to histograms of mass distributions.

34. R. L. Thews, Phys. Rev. 175, 1749 (1968).
36. The y axis is the normal to the production plane, defined by the cross product $\vec{k} \times \vec{p}$ of the directions of the photon and the vector meson. The x axis is given by $\hat{x} = \hat{y} \times \hat{z}$. The angle $\phi$ between the electric vector of the photon, $\hat{e}$, and the production plane in the total c.m. system is defined by:
\[
\sin \phi = \hat{y} \cdot \hat{e} \text{ with the sign ambiguity defined by } \cos \phi = \hat{e} \cdot (\hat{y} \times \hat{k}) \text{.}
\]
The decay angles $\theta$, $\phi$ are the polar and azimuthal angles of the direction of flight, $\hat{r}$, of the $\pi^+$ in the $\rho$ rest system:
\[
\begin{align*}
\cos \theta &= \hat{r} \cdot \hat{z} \\
\cos \phi &= \hat{y} \cdot (\hat{z} \times \hat{r}) / |\hat{z} \times \hat{r}| \\
\sin \phi &= -\hat{x} \cdot (\hat{z} \times \hat{r}) / |\hat{z} \times \hat{r}| \n\end{align*}
\]
42. We have checked the reliability of the errors on the $\rho_{ik}$ obtained from the
maximum likelihood analysis. To this end 1000 experiments with 100 s-channel helicity-conserving \( p^0 \) events were generated. In a maximum likelihood analysis the \( \rho_{ik} \) were determined separately for each experiment. The width of the distribution of the \( \rho_{ik} \) fitted for each experiment was found to be consistent with the error on \( \rho_{ik} \) as given by the maximum likelihood analysis.

44. Hontebeyrie \textit{et al.}, in a discussion of helicity conservation, have proposed a certain parameterization of the helicity amplitudes (M. Hontebeyrie, C. Meyers, J. Procureur and Ph. Salin, University of Bordeaux preprint PTB-40 (1971) (unpublished)). Using their parameterization and fitting the resulting density matrix to our 4.7 GeV data in the range \( 0.02 \leq |t| \leq 0.4 \text{ GeV}^2 \), we find \( p^0 \) helicity flip contributions to the cross sections of \( 6 (30\%) \) for \( t = 0.2 (0.4) \text{ GeV}^2 \). The helicity flip occurs almost entirely in the "double flip" terms d and f of Hontebeyrie, \textit{et al.}

45. The density matrix elements used in this fit are given by

\[
\rho_{ik} = d^{1}_{im}(\beta) \bar{\rho}_{mn} d^{1}_{nk}(-\beta)
\]

with \( \bar{\rho}_{11} = \bar{\rho}_{-1-1} = \frac{1}{2} \), \( \bar{\rho}_{1-1} = \bar{\rho}_{-11} = \frac{1}{2} \), \( \bar{\rho}_{11} = \bar{\rho}_{-1-1} = \frac{1}{2} \). Other \( \bar{\rho}_{mn} \) are zero. The rotation matrices \( d^{1}(\beta) \) describe a rotation through the angle \( \beta \) about the normal to the production plane. The \( \rho_{ik} \) were inserted in \( W(\cos \theta, \phi, \Phi) \) of Eq. (2) above and \( \beta \) was fitted using Eq. (1) of Appendix A.

46. All total cross sections for \( p^0 \) production given in this paper are corrected for the interval \( |t| < 0.02 \text{ GeV}^2 \). We fit the differential distribution to the form \( B e^{At} \); the cross section correction is then given by

\[
\int_{t_{\text{min}}}^{0.02} B e^{At} dt,
\]
where $t_{\text{min}}$ is the minimum momentum transfer required to produce the $\rho^0$. Differential cross sections have been fitted to the forms $e^{At}$ and $e^{At + Bt^2}$; both forms give equally good fits to the data. We give forward cross sections determined from both fits to indicate the dependence of the forward cross section on the type of extrapolation used.

54. This approach was suggested to us by D. Yennie (private communication).
55. This follows from using a $\rho$ Breit-Wigner of the form $\frac{M_\rho \Gamma_{\rho}}{(M^2 - M^2_{\rho})^2 + M^2_{\rho} \Gamma^2_{\rho}}$ whose integral is normalized to unity for $M_\rho \Gamma_{\rho} \rightarrow 0$.
56. Owing to the uncertainty in the determination of $d^2\sigma/dtdM$ a forward cross section estimated for a given $M_\rho, \Gamma_\rho$ is uncertain to about $\pm 10\%$. The relative positions of the lines for different $M_\rho$ are determined by the form of the curve used to fit $d^2\sigma/dtdM$ so this figure gives only a qualitative indication of the dependence of $d\sigma/dt$ on $M_\rho$.

The dual model has recently been reformulated to conserve s-channel
helicity at the $\gamma p$ vertex (P. Dewey and B. Humpert, University of Cambridge preprint HEP 71-2 (1971) unpublished). We find that this helicity conserving dual model fits the 4.7 GeV data well with a fitted $\rho^0$ mass and width of 761 MeV and 130 MeV respectively. The moments and density matrix elements agree well with the data. The predicted cross section for $\gamma p \rightarrow p\pi^+\pi^- (\Delta^{++} \text{excluded})$ is about 20% higher than that observed experimentally.

68. Their acceptance is $| \bar{Q} - Q | / \bar{Q} < 0.18$, $\bar{Q} = E_{\gamma}^{\text{max}} / 1.15$. For reasons of
   statistics we accepted all $\pi^+ \pi^-$ decay angles, whereas the DESY-MIT
group measured only a small fraction of the decay distribution around \( \theta_H = 90^\circ \). They then assumed a \( \sin^2 \theta_H \) distribution to obtain cross sections integrated over the decay angles. The experimentally observed \( \cos \theta_H \) distribution of the inelastic \( \pi^+\pi^- \) pairs in the \( \rho^0 \) region is roughly constant.

69. R. Talman, private communication.

70. G. McClellan et al., (Ref. 64) use a different \( \rho^0 \) mass and width from that used by us. Also they allow the phase of the \( \rho^0 \) and Drell terms to vary in order to fit the experimental mass distribution and do not take account of the \( t \)-dependence of the Drell terms. The Söding model of Alvensleben et al., (Ref. 65) takes into account neither the \( \pi\pi \) mass and momentum dependence of the Drell terms, nor the contribution from the Drell terms alone; neither do they use a rescattering correction. The ABBHMM collaboration (Ref. 11) determined only the total \( \rho^0 \) cross sections with the Söding model; in this determination no rescattering corrections were applied. In view of these differences published Söding model cross sections are not directly comparable. However, we may compare \( \rho^0 \) cross sections determined using the technique of Section IV-C3. We have compared the 4.7 GeV cross sections of Table XIII with those of the Cornell group at 5.5 GeV as given in the Ph.D. thesis of H. O. Ogren (Cornell University, Sept. 1970 unpublished). We have scaled the Cornell cross sections to the same \( \rho^0 \) width as used by us and have reduced their cross sections by 10% (see Fig. 24(f)) to take account of inelastic background; the resulting cross sections agree within errors with those of Table XIII in the interval \( 0.02 < |t| < 0.3 \text{ GeV}^2 \) while their cross sections at smaller \( |t| \) are higher than would be expected from a linear extrapolation of our data.
71. A Donnachie, R. G. Kirsopp, and C. Lovelace, CERN Report No. TH 838 (1967) (unpublished). We set $\delta_{33} = 0$ for $M > 1.8$ GeV.

83. This conclusion contrasts with that of Boyarski et al., (Phys. Rev. Letters 25, 695 (1970)) who find a discrepancy between their data and VDM calculations of a factor 2 to 5. As they point out, this could originate in their assumption that $A(\pi^+ p \rightarrow V^0 \Delta^{++}) = A(V^0 p \rightarrow \pi^- \Delta^{++})$, an assumption which is not made in the Gotsman analysis discussed here.

86. D. Yennie, private communication.

88. F. Gutbrod, private communication.

**Notes:**

- a $m > 0$
- b The number of events for hypotheses 4 do not include those events with a visible $K$-decay (7 at 2.8 GeV and 10 at 4.7 GeV for $\gamma p \rightarrow pK^+K^-$).
- c Includes events with unseen recoil protons.
- d Hypotheses 2,3 ambiguous are not included in hypotheses 2 and 3 above (similarly for hypotheses 1,4 ambiguous).
Table III

Cross sections for pair production on hydrogen, according to Knasel (Ref. 18), as a function of photon energy, $E_\gamma$.

### TABLE IX

$\Delta \phi/\Delta M$ min $\mu\mathrm{b}/\mathrm{GeV}^3$. Here $\Delta M$ is the interval, heading the column (no $e^{-}_{\min}$ correction has been made) and $\Delta M$ is $0.04 \mu\mathrm{b}/\mathrm{GeV}^3$; the lower limit of the $\Delta M$ interval is given in the first column of the table. Also given is $e^{-}_{\min}$ and $A$ from a fit of the form $Be^{-}A$ in the interval $t' < |t| < 0.4 \mathrm{GeV}^2$, where $t'$ is the larger of $e^{-}_{\min}$ and $0.02 \mathrm{GeV}^2$.

Table XI

Reaction $\gamma p \rightarrow pn^+ n^-$. Dipion total cross sections, differential cross sections at $t = 0$ and slope of differential cross sections (assuming the forms $d\sigma/dt\bigg|_{t=0} e^{At}$ and $d\sigma/dt\bigg|_{t=0} e^{At + Bt^2}$) from the intensity of the c.m.s. $s$-channel helicity-conserving p-wave state $T$, from the parameterization technique, and from the Söding model. The values of $d\sigma/dt\bigg|_{t=0}$, $A$ and $B$ were determined from fits to the differential cross section (Table XII) for $|t| < 0.4$ GeV$^2$.

The errors for the Söding model do not include the systematic uncertainties in the model assumptions used.

FIGURE CAPTIONS

1. Layout of the beam. The beam profile is shown in the horizontal and vertical planes (not to scale).

2. Photon energy spectra (unnormalized) for the 2.8 and 4.7 GeV runs. The arrows indicate the energy intervals used. The ordinate gives the number of photons.

3. Dipion mass from $514 K^0$ decays (combined data of the two energies).

4. Three-body cross sections from this experiment, from the ABBHHM collaboration (Ref. 26) and from the annihilation experiment (Ref. 28).

5. Missing mass squared distributions. Three-prongs: (a) 2.8 GeV $\gamma p \rightarrow p \pi^+ \pi^- MM$, (b) 4.7 GeV $\gamma p \rightarrow p \pi^+ \pi^- MM$, (c) 2.8 GeV $\gamma p \rightarrow \pi^+ \pi^+ \pi^- MM$ unique, (d) 2.8 GeV $\gamma p \rightarrow \pi^+ \pi^+ \pi^- MM$ ambiguous, (e) 4.7 GeV $\gamma p \rightarrow \pi^+ \pi^+ \pi^- MM$ unique, (f) 4.7 GeV $\gamma p \rightarrow \pi^+ \pi^+ \pi^- MM$ ambiguous. The curves are a sum of model predictions for multineutral production and background from misidentified events normalized to the data as explained in the text.

6. Missing mass squared distributions. Five-prongs: (a) 2.8 GeV $\gamma p \rightarrow p \pi^+ \pi^- \pi^- \pi^- MM$, (b) 4.7 GeV $\gamma p \rightarrow p \pi^+ \pi^- \pi^- \pi^- MM$, (c) 2.8 GeV $\gamma p \rightarrow \pi^+ \pi^+ \pi^- \pi^- \pi^- MM$, (d) 4.7 GeV $\gamma p \rightarrow \pi^+ \pi^+ \pi^- \pi^- \pi^- MM$ unique, (e) 4.7 GeV $\gamma p \rightarrow \pi^+ \pi^+ \pi^- \pi^- \pi^- MM$ ambiguous. The curves are a sum of model predictions for multineutral production and background from misidentified events normalized to the data as explained in the text.

7. Cross sections for 3-prongs with neutral(s) from this experiment and from the annihilation experiment (Ref. 28).

8. Reaction $\gamma p \rightarrow p \pi^+ \pi^-$. Dalitz plot distribution.

9. Reaction $\gamma p \rightarrow p \pi^+ \pi^-$. Chew Low plots for $\pi^+ \pi^-$, $\pi^0 p$, and $\pi^- p$. (c)-(f) are for $M_{\pi^+ \pi^-} > 1$ GeV. The outlined regions are shown on the right in an expanded scale.
10. Reaction $\gamma p \rightarrow p\pi^+\pi^-$. (a) $\pi^+\pi^-$ mass distributions for different $t$ intervals. The helicity-conserving p-wave intensity $I$ is shown by the points $\uparrow$. The curves give the results of maximum likelihood fits to the channel using the parameterization method (---) and the Söding model (---) described in appendices A and B respectively. (b) $p\pi^+$ and $p\pi^-$ mass distributions. The shaded histograms represent events with $|t_{p\rightarrow p\pi^\pm}| < 0.4 \text{ GeV}^2$ and $M_{\pi^+\pi^-} > 1 \text{ GeV}$. The curves are from a fit described in Appendix B.

11. Reaction $\gamma p \rightarrow p\pi^+\pi^-$. (a, b) $(d^2\sigma/dtdM)_{t=0}$ for dipion production obtained from a maximum likelihood fit of the form $B e^{At}$ to events in the $t$-interval $0.02 < |t| < 0.4 \text{ GeV}^2$. The solid curve is from a fit of the form Breit-Wigner $(M_{\rho}/M_{\pi\pi})^n$ (see Section IV-C3) in the interval $0.6 < M_{\pi\pi} < 0.9 \text{ GeV}$. (c, d) The slope, $A$, of the invariant momentum transfer distribution of dipion pairs as a function of dipion mass. The solid curve is from the Söding model (Section IV-C2 and Appendix B).

12. Angles used in the study of $\rho^0$ decay. The angle $\alpha$ is zero in the Gottfried-Jackson system.

13. Reaction $\gamma p \rightarrow pp\rho^0$ at (a) 2.8 GeV and (b) 4.7 GeV, respectively. Rho decay angular distributions in the helicity system without background subtraction. The curves are proportional to $\sin^2 \theta_H$ and $(1 + P_\gamma \cos 2 \Psi_H)$.

14. Reaction $\gamma p \rightarrow p\pi^+\pi^-$. The dipion moments $Y_1^0(\theta)$, $Y_2^0(\theta)$, Re $Y_2^2(\theta,\Psi)$, $Y_3^0(\theta)$, $Y_4^0(\theta)$, $Y_6^0(\theta)$ in the helicity frame as a function of $M_{\pi^+\pi^-}$ for $0.02 < |t| < 0.4 \text{ GeV}^2$. The curves are obtained from the Söding model (Section IV-C2).

15. Reaction $\gamma p \rightarrow p\pi^+\pi^-$. Helicity frame density matrix elements and parity asymmetry as a function of dipion mass for $0.02 < |t| < 0.4 \text{ GeV}^2$. The curves are obtained from the Söding model.

16. Reaction $\gamma p \rightarrow p\rho^0$. The spin density matrix parameters as a function of $t$ in the Gottfried-Jackson, helicity and Adair systems.
17. Reaction $\gamma p \rightarrow p\rho^0$. The angle $\beta$ for rotation about the normal to the production plane of the $\rho$ density matrix from the helicity frame into the "minimum flip" system as a function of $t$. The curves marked H, A, GJ show where the data points would lie if the minimum flip system were the helicity, Adair and Gottfried-Jackson frame, respectively.

18. Reaction $\gamma p \rightarrow p\rho^0$. The parity asymmetry, $P_\sigma$, and the asymmetry, $\Sigma$, as a function of $t$. The points labeled DESY and Cornell are from Refs. 40 and 41, respectively.

19. Reaction $\gamma p \rightarrow p\rho^0$. Differential cross sections as a function of $t$ for the helicity-conserving p-wave contribution $\Pi(\frac{1}{2})$, for $\rho^0$ production as obtained from fits with the Söding model $\Pi(\frac{1}{2})$ and from the parameterization $(M_\rho/M_{\pi\pi})^n(t)$ $(\frac{1}{2})$. The shaded regions are shown above on an expanded scale.

20. Fitted values for $n(t)$ using the parameterization $(M_\rho/M_{\pi\pi})^n(t)$. (For details see Appendix A.)

21. The fitted ratio of the $\rho^0$ to Drell cross sections, $\sigma_\rho(t)/\sigma_{\text{Drell}}(t)$. The solid (dashed) curves show the predictions of the Söding model with the Ferrari-Selleri (Benecke-Dürr) form factor. Note that the Drell amplitude does not include $\Delta^{++}$ production.

22. The experimental forward differential $\rho^0$ cross section, $(d\sigma/dt)_{t=0}$, determined using a phenomenological Söding model (Section IV-C3), as a function of $\rho^0$ mass and width. Errors in $(d\sigma/dt)_{t=0}$ are discussed in footnote 56.

23. Reaction $\gamma p \rightarrow p\pi^+\pi^-$. $d^2\sigma/d\Omega dM$ in the forward direction from this experiment compared with that from the DESY-MIT experiment (Ref. 65).
24. (a, b) The mass distribution of inelastic $\pi^+\pi^-$ pairs for $Q_T^2 < 0.05 \text{ GeV}^2$ (see text for the restrictions applied). (c, d) The distribution of the momentum, $Q$, of elastic (---) and inelastic (---) $\pi^+\pi^-$ pairs for $0.6 < M_{\pi\pi} < 0.9 \text{ GeV}^2$. (e, f) Contamination of $\pi^+\pi^-$ pairs from the reaction $\gamma p \rightarrow p\pi^+\pi^-$, $\pi\pi_{\text{elas}}$, by inelastic $\pi^+\pi^-$ production, $\pi\pi_{\text{inelas}}$, (i.e., from reactions other than $\gamma p \rightarrow p\pi^+\pi^-$). The $\pi\pi$ pairs are in the interval $0.6 < M_{\pi\pi} < 0.9 \text{ GeV}$ (for other restrictions see text) and the ratio $R = \pi\pi_{\text{elas}} / (\pi\pi_{\text{elas}} + \pi\pi_{\text{inelas}})$ is plotted versus the square of the transverse momentum, $Q_T^2$.

25. The differential cross section for $\rho^0$ production: from this experiment (●) at 4.7 GeV using the parameterization technique; from the ABBHHM collaboration at 4.5 - 5.8 GeV (●) (Ref. 11); from Anderson et al., (●) at 6 GeV (Ref. 67).

26. Reaction $\gamma p \rightarrow p\pi^+\pi^-$. $\pi^+\pi^-$ mass distribution for the combined data at 2.8 and 4.7 GeV. The curves give the results of maximum likelihood fits with (---) and without (---) $\rho^0$-$\omega$ interference.

27. Reaction $\gamma p \rightarrow \Delta^{++}\pi^-$. Differential cross sections $d\sigma/dt$ from this experiment (●) and from Ref. 73 for $E_\gamma = 5 \text{ GeV}$ (●). The shaded regions in (b), (d) are shown on an expanded scale in (a), (c). The curves are the predictions of the gauge-invariant OPE model with absorption corrections for $C=0.8$ (---) and $C=1$ (---). The points (○) are the VDM prediction of Ref. 82.

28. Reaction $\gamma p \rightarrow \Delta^{++}\pi^-$. Density matrix parameters and parity asymmetry $P_\sigma$. The solid curves are the predictions of the gauge-invariant OPE model with absorption corrections for $C=0.8$. The dashed-dotted curves show the VDM predictions (Ref. 82).
29. Diagrams for the reaction $\gamma p \to p\pi^+\pi^-$ corresponding to the Söding model:
(a) diffractive $\rho$ production, (b) Drell diagrams, (c) rescattering correction to the Drell diagrams.

30. The contributions of rho, Drell, interference terms, phase space and $\Delta^{++}$ to the $\pi^+\pi^-$ mass spectrum from a Söding model fit to the channel $\gamma p \to p\pi^+\pi^-$ in the region $0.02 < |t| < 0.4$ GeV$^2$. The lower diagrams give the contributions in the intervals $0.02 < |t| < 0.08$ GeV$^2$ and $0.18 < |t| < 0.4$ GeV$^2$.
