Abstract

In animal models of hepatocellular carcinoma (HCC), deficiency of S-adenosylmethionine (SAMe) increased the risk of HCC whereas administration of SAMe reduced HCC. The aim of this trial was to determine whether oral SAMe administration to patients with hepatitis C cirrhosis would decrease serum α-fetoprotein (AFP) level, a biomarker of HCC risk in hepatitis C. This was a prospective, randomized, placebo-controlled, double-blind trial of SAMe, up to 2.4 g/d, for 24 weeks as compared with placebo among subjects with hepatitis C cirrhosis and a mildly elevated serum AFP. Primary outcome was change in AFP between baseline and week 24. Secondary outcomes included changes in routine tests of liver function and injury, other biomarkers of HCC risk, SAMe metabolites, markers of oxidative stress, and quality of life. One hundred ten subjects were randomized and 87 (44 SAMe and 43 placebo) completed treatment. There was no difference in the change in AFP during 24 weeks among subjects receiving SAMe as compared with placebo. Changes in markers of liver function, liver injury, and hepatitis C viral level were not significantly different between groups. Similarly, SAMe did not change markers of oxidative stress or serum glutathione level. SAMe blood level increased significantly among subjects receiving SAMe. Changes in quality of life did not differ between groups. Overall, this trial did not find that SAMe treatment improved serum AFP in subjects with advanced hepatitis C cirrhosis and a mildly elevated AFP. SAMe did not improve tests of liver function or injury or markers of oxidative stress or antioxidant potential.

Introduction

The incidence of hepatocellular carcinoma (HCC) in the United States increased approximately 3-fold between 1980 and 2010 and is estimated to increase by another 50% between 2010 and 2020 (1, 2). This increase is primarily due to the development of cirrhosis and HCC among Americans infected with hepatitis C between 1965 and 1990 (1). Curing hepatitis C virus (HCV) decreases the incidence of HCC (3, 4). However, the cost of HCV treatment is high and the availability of inexpensive drugs that decreased the incidence of HCC would be useful.

S-adenosylmethionine (SAMe) is synthesized from methionine and ATP and is a substrate for several biochemical pathways (5, 6). These include the aminopropylation pathway in which the aminopropyl moiety of SAMe is used to synthesize polyamines, transmethylation pathways in which the methyl group (CH3) of SAMe is transferred to an acceptor molecule such as nucleic acids, proteins, phospholipids, biologic amines or other small molecules, and the trans-sulfuration pathway in which homocysteine is converted into glutathione. Oral SAMe has been available in the United States as a nutritional supplement for more than 10 years. It has an excellent safety profile, with gastrointestinal side effects occurring in a minority of subjects (7).

Several studies suggest that SAMe might be important in the development of HCC. SAMe deficiency, created by feeding a...
methionine choline–deficient (MCD) diet, is hepatocarcinogenic in rats and several strains of mice (8–10). More importantly, SAMe administration reduces liver cancer in a chemical model of HCC in rats, suggesting a potential chemopreventive use (11, 12).

α-Fetoprotein (AFP) has been used as a serum marker for HCC for the past 40 years (13). Although AFP is not directly involved in the carcinogenesis pathway, multiple studies have shown an association between increased serum levels of AFP and increased risk for subsequent development of HCC (14, 15).

The current study evaluated the effect of oral SAMe for 24 weeks, at doses up to 2.4 g/d, on serum AFP in patients with advanced hepatitis C and a mildly elevated serum AFP level. Secondary outcomes included the effect of SAMe on other markers of liver function/injury, markers of oxidative stress, other biomarkers of HCC risk, quality of life, and metabolites in the methionine cycle. A dose of 2.4 grams of SAMe was selected for study because it represented the highest dose that could be easily tolerable from a pill burden perspective (3 tablets twice a day).

Materials and Methods

From 2007 to 2012, we enrolled subjects 18 years of age or older who had chronic hepatitis C infection and evidence of advanced liver fibrosis based on liver biopsy or a platelet count less than 150,000/mm³ or an aspartate aminotransferase/alanine aminotransferase (AST/ALT) ratio > 0.75, who also had a serum AFP level at their clinical laboratory between 15 ng/mL (~50% greater than the upper limit of normal) and 100 ng/mL. All patients had a recent radiologic examination of the liver that excluded a liver mass suggestive of HCC and had not received treatment for hepatitis C in the prior 4 months and agreed to refrain from HCV treatment during the study period. Exclusion criteria included liver disease other than hepatitis C, mass in the liver suggestive of possible HCC within the prior 6 months, model for end stage liver disease (MELD) score > 15, hospitalization in the prior 5 years for mania or bipolar disorder, use of a monoamine oxidase inhibitor, or other serious condition that interfered with patient’s ability to complete the study.

Study design and oversight

This was a randomized, double-blind, placebo-controlled clinical trial in which patients were randomized 1:1 to receive SAMe or placebo for 24 weeks. SAMe was donated by Gnosis S.p.A. and packaged in individual blister packs by Generic Pharmaceutical Services, Inc. SAMe was administered as a 400-mg tablet, taken orally twice a day. For the first 4 weeks, patients consumed 400 mg (1 tablet) twice a day (800 mg/d). The dose was increased to 2 tablets twice daily (1,600 mg/d) for weeks 5 through 8 and further increased to 3 tablets twice daily (2,400 mg/d) for weeks 9 through 24. Patients randomized to placebo consumed matching placebo at the same frequency. All patients were prescribed a multivitamin tablet (B-50) containing vitamin B₆, B₁₂, and folic acid (Pharmavite) to consume daily during the 24 weeks; these vitamins are required cofactors for the conversion of homocysteine (Hcy) to methionine (by the enzyme, methionine synthase) or to cystathionine (initial step in trans-sulfuration pathway). Patients were seen in clinic every 4 weeks for 24 weeks (end of treatment) and again at week 30 for an end of study visit. At each clinic visit, patients were assessed for medication compliance and adverse events, and blood was obtained for safety laboratory tests and study outcomes. Quality of life was assessed at weeks 0, 12, 24, and 30 using the short form (SF)-36 and the chronic liver disease questionnaire (CLDQ; ref. 16). Three clinical sites started the study. Because of low enrollment, 2 enrollment sites were added.

The study was designed by the primary author in consultation with the University of California-Irvine (UCI) Chao Family Comprehensive Cancer Center (CFCCC) and the study sponsor (Division of Chemoprevention, NCI, Bethesda, MD) in accordance with Good Clinical Practice guidelines, the principles of the declaration of Helsinki and applicable regulations. The Data Safety Monitoring Board for the UCI CFCCC reviewed the conduct of the study annually. The study was approved by the Institutional Review Board (IRB) at each study site prior to patient enrollment. All patients provided written informed consent. The site investigators gathered the data and the UCI CFCCC conducted the data analysis. All authors participated in the development of the article.

Efficacy and safety assessments

Blood for liver function tests and for safety laboratories [complete blood count (CBC), basic metabolic panel (BMP)] was analyzed at the clinical laboratory at each participating hospital. Serum was also frozen and assayed subsequently in batches for AFP, AFP lectin-3 (AFP-L3), and des-gamma-carboxy prothrombin (DCP; wby Wako Laboratories), for SAMe, SAH, and methionine (17). For total homocysteine (Hcy) and glutathione (GSH; ref. 18) for serum markers of oxidative stress [malondialdehyde (MDA) and, 4-hydroxynonenal (4-HNE; Cell Biolabs Inc.) and serum level of HCV ribonucleic acid (RNA; COBAS TaqMan HCV test; Roche Molecular Systems)]. SF-36 and CLDQ were performed and scored as recommended. The site investigator classified the severity of adverse events as mild, moderate, or severe and determined the relationship to the study medicine. Adverse events (AE) were categorized for severity and body site in accordance with the Common Terminology Criteria for Adverse Events (CTCAE), version 3.0.

Endpoints

The primary efficacy endpoint was change in serum AFP between start of treatment (W0) and end of treatment (W24). Secondary outcomes included change in routine liver blood tests, HCV RNA level, other serum markers of HCC (AFP-L3, DCP), SAMe metabolites, serum markers of oxidative stress, and quality of life.

Statistical analysis

The primary statistical hypothesis of the study was that SAMe treatment for 24 weeks would decrease the serum AFP level. The sample size was based on preliminary data showing an expected mean AFP level in the study group of 35 ng/mL (SD, 20 ng/mL). An effect size of 12 ng/mL (~33% reduction) was selected and the correlation between the pre- and postintervention measurements was assumed to be 0.5. With 40 subjects per treatment arm, power was estimated at 80% to detect with significance level of 0.05, a reduction in serum AFP of 11.7 ng/mL, assuming no change in the control group, using a univariate, 2 group repeated measures ANOVA model. We anticipated a 10% drop out rate and therefore proposed 45 patients/group (total study size, 90 subjects).

All subjects who completed the week 24 visit as planned were included in the data analysis. The number of subjects in each analysis differed slightly because the number of subjects with data
at both time points (i.e., weeks 0 and 24) varied depending on the outcome measured.

Changes in serum AFP and other laboratory values from weeks 0 to 24 were compared between treatment arms using 2-group t tests with 2-sided significance level of 0.05. For any measures that were not normally distributed (SAMe, SAH, and SAMe/SAH), a Mann–Whitney nonparametric test was used. Repeated measures ANOVA methods were used to compare trends over time between treatment arms for those with complete data at all visits. Change in quality of life domains and subdomains were compared using 2-group t tests. No adjustments were made for multiple comparisons.

Results

A total of 147 patients were screened and 110 were randomized, 57 to the treatment group and 53 to placebo control (Fig. 1). The baseline demographic and laboratory data were similar in the 2 treatment groups with no significant differences between arms (Table 1). Twenty-three subjects were excluded after randomization, 13 receiving SAMe (8 adverse events, 4 noncompliant, and 1 lost to follow-up) and 10 receiving placebo (3 noncompliant, 3 adverse events, 1 lost to follow-up, 1 withdrew consent, 1 ineligible, and 1 other). A total of 87 patients (43 receiving placebo and 44 receiving SAMe) completed the 24 week treatment (Fig. 1).

Between week 0 and week 24, serum AFP as measured by Wako laboratories decreased from 34.6 to 32.7 ng/mL in subjects receiving SAMe but increased from 35.8 to 41.7 ng/mL in subjects receiving placebo (difference between arms = 7.78, P = 0.16; Table 2). When data were analyzed including only subjects with complete data at all visits (n = 83), a similar nonsignificant difference between arms was observed for change over time in serum AFP (P = 0.13; Fig. 2). Results did not change when data from local laboratories were used or when restricted to good compliers with no dose reduction (data not shown). There was considerable variation across sites, with AFP decreasing following SAMe treatment at 4 of the 5 sites (mean difference between arms, 15.18 ng/mL for 41 subjects, P = 0.057). However, at the site with the largest patient enrollment (n = 42), there was no difference between treatment arms (Fig. 3). Adjustment for multiple baseline and treatment variables (e.g., SAMe blood levels, compliance, baseline tests of liver disease severity, etc.) did not explain the difference in response to SAMe among the study sites.

Abbreviation: INR, international normalized ratio.
AFP-L3 and DCP were available in a subset of patients (26 placebo and 27 SAMe). Changes in DCP and AFP-L3 between week 0 and week 24 did not differ significantly between the SAMe and the placebo arms (Table 2). Similarly, blood levels of the oxidative stress markers MDA and 4-HNE did not change with SAMe treatment (Table 2). Treatment and control groups did not differ significantly with respect to change over time for levels of routine blood tests for liver function and liver injury or in HCV RNA level (Supplementary Table S1).

Compliance with medication consumption, as assessed by pill count at each clinic visit, was excellent among the 87 subjects who completed the week 24 visit (Supplementary Table S2). Mean SAMe plasma level increased over time among subjects randomized to SAMe as compared with placebo (Table 2), with stepwise increase in SAH with each increase in SAMe dose (data not shown). SAM/SAH ratio regulates the activity of enzymes that use SAMe in methylation reactions, with a lower ratio signifying slower reactions. Among subjects receiving SAMe, the SAMe/SAH ratio increased from 3.31 at week 0 to 8.62 at week 24 but remained unchanged among subjects receiving placebo (3.45 at W0 and 3.54 at W24; Mann–Whitney test, \( P < 0.001 \); Table 2). Change in plasma levels of homocysteine, methionine, and total glutathione between week 0 and week 24 did not differ between subjects receiving SAMe and subjects receiving placebo (Table 2).
Quality of life was assessed using the SF-36 and CLDQ questionnaires. All 110 subjects completed baseline questionnaires. While there were no significant differences between treatment arms in change from weeks 0 to 24 for either the SF-36 physical or mental component scores ($P = 0.88$ and $P = 0.21$, Supplementary Table S2 and Supplementary Fig. S1), data suggest an improvement in mental well-being in the treatment arm. Subjects treated with SAMe reported a nonsignificant improvement over 24 weeks in the mental component score relative to controls and a significant improvement in the mental health subdomain (treatment A − 200 0 200 400 600 800 1,000 1,200 1,400 1,600 1,800 2,000 Mean SAMe (ng/mL) Week Mean SAMe from week 0 to week 30 0 4 81 612 20 24 30 Treatment by time interaction: $P < 0.001$

Figure 4. Serum SAMe. A, serum SAMe at all study time points among subjects randomized to SAMe or placebo shows that SAMe increased significantly among subject receiving SAMe, but not among subjects receiving placebo, and that serum SAMe level returned to baseline by week 30. B, serum SAMe levels increased between week 0 and week 24 among subjects randomized to SAMe but did not increase among subjects randomized to placebo.

NOTE: Includes subjects with at least one follow-up visit after randomization. Rows are not mutually exclusive.

*The P value of the Fisher exact test.

by time interaction: \( P = 0.24 \) and \( P = 0.04 \) respectively; Supplementary Table S2). One hundred six subjects (52 placebo and 54 SAMe) completed the baseline CLDQ. There were no significant differences between treatment arms in change over time for the CLDQ summary score or in subdomains (Supplementary Table S2). Trends over the 24 weeks showed a nonsignificant improvement in the CLDQ for the treatment arm relative to controls (\( P = 0.18 \) for treatment by time interaction; Supplementary Fig. S2).

Table 3 lists treatment-emergent adverse events, including those that were assessed as related or not related to the study medication. Inclusion of a placebo arm allows for comparison of frequency of adverse events between groups. Approximately 88% (97 of 110) of subjects had one or more grade 1 or higher adverse event, 42% (46 of 110) had grade 2 or higher, and 9% (10 of 110) had grade 3 or higher, with no difference in frequency or severity of adverse events between treatment groups. Nausea was significantly more common among subjects receiving SAMe, whereas constipation, diarrhea, fatigue, and abdominal cramps/pain were numerically more frequent. Eight subjects receiving SAMe discontinued treatment because of adverse events, 5 of which were gastrointestinal [nausea (2), diarrhea (2), abdominal discomfort (1)]. Three subjects receiving placebo discontinued treatment, 2 due to gastrointestinal symptoms [gas (1), flatulence (1)]. There were 7 serious adverse events among 5 subjects receiving SAMe and 4 serious adverse events among 3 subjects receiving placebo (not significant; Table 3). None was assessed by the investigator to be related to study drug treatment. Thirteen subjects in the SAMe group reduced their medications because of adverse events as compared with 5 subjects receiving placebo. Adverse events occurred at all 3 dose levels of SAMe (i.e., 800, 1,600, and 2,400 mg/d).

Discussion

This study found a nonsignificant improvement in AFP among subjects with hepatitis C and advanced liver disease who received SAMe for 24 weeks as compared with subjects who received placebo. The choice of the maximal dose of SAMe, 2.4 g/d, was empiric. The typical dose of SAMe is between 400 and 1,600 mg/d when prescribed as a medicine in other countries; the daily dose in the United States is unknown but is likely less than 1,000 mg/d given that the typical tablet size is 200 to 400 mg. We elected to give as high a dose of SAMe as reasonably tolerable and within safety limitations. A dose of 2.4 g/d was selected because it corresponded with 3 tablets twice a day, an amount that was thought to be generally tolerable, without causing “pill burden.”

SAMe treatment was associated with a decrease in serum AFP at week 24, when compared with placebo treatment, at 4 of the 5 treatment sites. However, SAMe treatment did not decrease serum AFP at the site with the largest subject enrollment (~50% of enrolled subjects). We could not identify differences in patient characteristics or laboratory data of liver disease injury or severity or in SAMe blood levels (medicine compliance or absorption) that could explain the different AFP responses to SAMe treatment. The apparent discordant results between the highest enrolling site and the aggregate of the other sites could reflect an underlying, but
not easily determined, difference in conditions that affected the metabolism of SAMe.

The lack of effect of SAMe in reducing AFP was not due to inability of SAMe to be absorbed. SAMe blood levels increased markedly among subjects randomized to SAMe, and the increase persisted throughout the 24-week treatment duration. The elevated SAMe levels returned to baseline by 6 weeks after stopping the SAMe.

The reason for lack of effectiveness of SAMe in this study, as compared with its efficacy in decreasing HCC in chemical-induced carcinogenesis in animal models, is unknown, although several explanations are possible. Chemical carcinogens in animal models of HCC directly interfere with SAMe metabolism, resulting in significant decreases in hepatic SAMe and in SAM/SAH ratio—and the decrease in SAMe levels in the dysplastic nodules and in HCC continues after the carcinogen administration is discontinued (12, 19–22). Administration of SAMe to the mice that received chemical carcinogens restores hepatic SAMe level and hepatic SAM/SAH ratio, which is associated with a decrease in the number of preneoplastic liver lesions and the prevention of dysplastic nodules and HCC and is associated with a decrease in labeling index and an increase in apoptosis in preneoplastic cells (11, 12, 20–22). The mechanism by which chemical carcinogens are hypothesized to promote HCC is through global DNA hypomethylation, especially hypomethylation (activation) of oncogenes. In an animal model of transplantation of human HCC cell lines into mice liver, SAMe administration decreased the growth of transplanted HCC by increasing apoptosis and reducing angiogenesis (23). The growth of transplanted HCC is increased in oncogene expression, increased hepatocyte proliferation, and increased hepatocyte survival; SAMe administration restores hepatic SAMe level and reverses these changes.

The mechanisms of hepatocellular development in chronic hepatitis C are incompletely understood but are believed to involve different, as well as more complex, pathways than those described for chemical carcinogenesis. Deficiency of SAMe has been described in the liver in chronic hepatitis C, although the magnitude of deficiency, as compared with the deficiency in chemical-induced carcinogenesis in animal models, is unclear (24). There appears to be several additional carcinogenic pathways in hepatocarcinogenesis, hepatic SAMe level is decreased and this decrease is believed to contribute to carcinogenesis through increased oncogene expression, increased hepatocyte proliferation, and increased hepatocyte survival; SAMe administration restores hepatic SAMe level and reverses these changes.

SAMe administration increased the blood level of SAH, the product of SAMe-dependent methyltransfer reactions. The increase in SAMe and SAH, as expected, led to an increase in the SAMe/SAH ratio in serum. We do not have biochemical measures of SAMe metabolites other than circulating serum levels of those in the methionine cycle. Thus, we cannot assess whether oral SAMe altered DNA methylation or other intracellular biochemical methylation–dependent pathways that use SAMe and are regulated by SAH.

SAMe did not alter other downstream metabolites of the methionine cycle. In particular, homocysteine, which is the immediate downstream metabolite of SAH, was not significantly elevated in subjects receiving SAMe, possibly due to a high rate of turnover in the metabolism of homocysteine. However, this finding is theoretically advantageous as elevated homocysteine levels have been associated with increased risk for atherosclerosis, stroke, and cardiovascular events such as cardiac ischemia and myocardial infarctions (29–31). Methionine, which is the downstream metabolite of homocysteine, was also not increased. This is also somewhat unexpected, as cirrhotics are reported to not metabolize methionine as well as control subjects (32, 33) and the cirrhotic subjects in this study were receiving approximately 2 grams of extra SAMe per day, of which approximately two thirds is metabolized via transmethylation and a portion recycled to methionine (34). Our findings that SAMe increased plasma SAMe and SAH, without increasing homocysteine or methionine levels, are similar to a previous report of a 6-week study of oral SAMe, 1,600 mg/d, in patients with depression (35).

SAMe is also the precursor of glutathione via trans-sulfuration of homocysteine (5, 36). Patients with cirrhosis are reported to have low glutathione levels (36), and a prior study of SAMe administration in cirrhosis reported increased plasma glutathione levels with SAMe administration (37). However, we were unable to confirm that SAMe increased plasma glutathione levels. The effect of SAMe on intracellular glutathione levels, and on mitochondrial glutathione levels in hepatocytes, was not investigated in this study.

One mechanism by which SAMe is hypothesized to be beneficial is by reducing oxidative stress. We could not demonstrate that SAMe altered plasma level of 4-HNE, a marker of protein oxidative stress, or MDA, a measure of lipid oxidative stress (lipid peroxidation). The lack of effect of SAMe on oxidative stress is consistent with the lack of detectable change in plasma glutathione level. However, these findings are limited because we measured serum levels of oxidative stress, not levels of intracellular oxidative stress.

SAMe administration did not affect routine blood tests of liver function (e.g., bilirubin, albumin) or liver injury (e.g., AST, ALT), nor did it affect the level of HCV RNA in the blood. SAMe has been recommended as a treatment for several types of liver disease, with reports of improvement in routine tests of liver function. SAMe administration for 2 years improved survival among subjects with advanced alcoholic cirrhosis, although the mechanism by which SAMe improved survival was not described (38). Tests of liver injury (e.g., ALT and AST) in patients with hepatitis can change quickly when patients are treated with drugs that inhibit the HCV. Consequently, it is reasonable to expect that AST or ALT would have changed during the 24-week treatment period if SAMe had an effect on liver injury or hepatitis C viral replication. Thus, our finding of lack of effect of SAMe on these measures, in more than 40 patients treated for 24 weeks, suggests that the effects of SAMe...
on liver function in hepatitis C cirrhosis are minimal or difficult to
detect with routine blood tests.
Tolerability of SAMe was reasonable. Gastrointestinal side
effects (nausea, abdominal pain, constipation, diarrhea) were
more frequent among subjects receiving SAMe, and several
patients were unable to tolerate SAMe because of gastrointestinal
symptoms. Nevertheless, the majority of patients tolerated 2.4
grams of SAMe per day, and many of the common adverse events
among subjects receiving SAMe were also noted among subjects
receiving placebo. Numerically more patients receiving placebo
than receiving SAMe required dose reductions because of adverse
events, although none of the serious adverse events was assessed
by the study investigator as related to SAMe.

SAMe has been extensively evaluated as a treatment for depres-
sion with inconsistent results (39). We did not directly measure
depression, but we did measure quality of life using the SF-36, a
widely used and general questionnaire of quality of life, and the
CLDQ, a quality of life instrument for patients with liver disease.
We were not able to demonstrate an effect of SAMe on either the
physical or mental component scores of the SF-36. However,
SAMe did improve the mental health subdomain, suggesting a
possible effect on depression. SAMe did not improve the overall
CLDQ score, nor did it alter any of the subdomains when
compared with placebo. Although our patients with hepatitis C
had higher scores on the SF-36 than the general U.S. population
(mean score of 50), prior studies of patients with hepatitis C and
advanced liver disease tend to report lower quality of life and
more depression, possibly because of patients’ decreased func-
tional status and potential limitation in life expectancy (40, 41).
Overall, SAMe does not appear to improve quality of life in
patients with advanced hepatitis C. Whether SAMe is effective as
a treatment for depression in patients with hepatitis C will need to
be tested using depression-specific instruments.

In summary, SAMe administration, at doses up to 2.4 g/d for 24
weeks, failed to improve the blood level of AFP, a biomarker of
HCC risk, in patients with hepatitis C and advanced liver disease.
SAMe administration increased blood level of SAMe and of SAH,
the major metabolite of SAMe in the methionine cycle. However,
oral SAMe did not alter the blood level of homocysteine, methi-
onine, or glutathione, all of which are downstream metabolites of
SAH in the methionine cycle or the trans-sulfuration pathway.
Blood levels of routine biochemical tests of liver function and of
liver injury were not altered by SAMe administration. Likewise,
blood levels of oxidative stress were not affected by SAMe.
SAMe did not change quality of life, although it did improve the
mental health subdomain of the SF-36. SAMe was generally well
tolerated. Overall, this study failed to suggest that SAMe should be
further tested as a chemopreventive agent against HCC among
patients with advanced hepatitis C. The study also suggests that
SAMe is unlikely to reduce liver injury or improve function in
patients with HCV cirrhosis.

Disclosure of Potential Conflicts of Interest
