ABSTRACT

A brief summary is made of the advantages of angular correlation involving conversion electrons and of the current state of experimental apparatus. It is emphasized that L conversion electrons in addition to K will provide important information of nuclear structure and the conversion process. Preliminary measurements on the 333 \( \gamma \rightarrow 356 \) K, L, M and 333 K, L, M \( \rightarrow 356 \) \( \gamma \) angular correlations in Pt\(^{195}\) are reported. A discussion is made of a possible rearrangement effect on the conversion coefficients of a nuclear transition which follows a converted transition in cascade.
I. INTRODUCTION

Angular correlations involving internal conversion electrons are important quantities in investigating nuclear structure and the conversion process. They provide the following information which is not obtained from $\gamma-\gamma$ angular correlations.

1) Whereas it is essentially impossible to discriminate between EL and ML transitions with $\gamma-\gamma$ angular correlation, the dependence of both particle parameter and conversion coefficient on multipolarity allows such a discrimination to be made in angular correlations involving internal conversion electrons. This advantage has been applied to unique determinations of spins and parities of the levels and multipolarities involved in a sequence. For example, $\gamma-\gamma$ angular correlation cannot discriminate between the two cases: 1) $4^+(E2) 2^+(E2) 0^+$ and 2) $2^+(E2 + M1, \delta = -0.19)$ $2^+(E2) 0^+$. On the other hand, $e^-\gamma$ angular correlation gives quite different values for these cases. A typical experiment was performed by Sakai et al. on the unique assignment of the $4^+(E2) 2^+(E2) 0^+$ sequence in Hg.

2) Since both particle parameter and conversion coefficient reflect the penetration effect, $e^-\gamma$ angular correlation provides additional information about this effect, independent of that obtained from conversion coefficient measurements. A series of experiments in this direction have been performed by the Uppsala group and others.
3) As first proposed by Church, Rose and Weneser, \( ^7 \) e\(-\)\( \gamma \) angular correlation is effected by a small admixture of EO component in direct competition with E2 and M1 multipole radiations. Experiments of this type have been carried out on Pt\( ^{196} \) by the Uppsala group, on Os\( ^{188,190} \), Pt\( ^{196} \), and Hg\( ^{198} \) nuclei by the Tokyo group, and on Pt\( ^{192} \) by Butt and Dutta. It is worth pointing out that the three independent experimental quantities, \( A_2(\gamma-\gamma) \), \( A_2(e^-\gamma) \) and \( \alpha_K \), are still insufficient to determine \( q(\text{EO/E2 mixing ratio}) \) and \( \lambda(\text{penetration parameter}) \) uniquely. This point will be discussed later in connection with the possibility of using L conversion electrons.

4) In the past, when there was no high-resolution gamma-ray spectrometer applicable to angular correlation experiments, e\(-\)\( \gamma \) angular correlation used to have another merit in that a magnetic spectrometer could be used to resolve closely spaced lines. The recent development of lithium-drifted germanium gamma-ray spectrometers seems to have made this feature less important.

II. DEVELOPMENT OF e\(-\)\( \gamma \) ANGULAR CORRELATION APPARATUS

In the past, there were two kinds of e\(-\)\( \gamma \) angular correlation apparatus. One used a magnetic lens spectrometer for an electron channel, and the other used a sector-type double-focusing spectrometer. The former was developed by the Uppsala group and many others. In general a lens-type spectrometer has a transmission larger than any other type of magnetic spectrometers, while the resolution is not as good. Furthermore, the aperture of the beam is so large that the geometrical attenuation factor is considerable.
The latter was developed by Sakai, Ikegami and Yamazaki. In spite of its small transmission ($< 0.5\%$ of $4\pi$) the sector-type double-focusing spectrometer has the following advantages: 1) the source is placed completely outside of the magnetic field. This makes it easier to connect a scintillation counter or another magnetic spectrometer to this. 2) It accepts a pencil beam from the source. In other words, it acts as a small rectangular-shaped detector. Therefore, the geometrical attenuation is not as great as that found in using a lens-type spectrometer. 3) It has a good characteristic of resolution versus transmission. The rectangular shape of the source is also suitable for angular correlation measurements.

A schematic view of the electron-electron spectrogoniometer, which was constructed at the Institute for Nuclear Study of University of Tokyo, is shown in Fig. 1. This apparatus is capable of a large variety of measurements, such as two independent $e^-\gamma$ angular correlations, $\gamma\gamma$ angular correlation and $e^-e^-$ angular correlation.

Recently modern apparatus making use of solid-state detectors have been developed by many people. The resolution of a Si(Li) detector is so good that it can replace a magnetic spectrometer in most cases. The main restriction in the use of Si(Li) detectors is that the total counting rate be limited. So it is not suitable to negatron emitters, in which case the conversion line of interest is only a small part of the large amount of continuous beta rays. The limited size of Si(Li) detectors also restricts the size of the source very much. A lithium-drifted germanium detector can resolve two gamma rays of 3 keV separation in energy. This detector is, indeed, an epoch-making device also in angular correlation experiments.
It not only resolves complicated gamma rays but also eliminates troubles caused by scattering because of its high energy discrimination.

Figure 2 shows a schematic view of a new apparatus adopting Si(Li) and Ge(Li) detectors, which is being constructed by Yamazaki and Hollander at the Lawrence Radiation Laboratory of the University of California and is partly in operation. A 3 cm x 2 cm x 10 mm deep Ge(Li) crystal is used as fixed gamma-ray counter and a 14 mm x 3 mm thick Si(Li) as a fixed electron spectrometer. When high resolution is required for the electron channel, in such a case as in resolving L subshell lines, the Si(Li) detector can be replaced by the Berkeley 50-cm radius π√2 type iron-free spectrometer. The detector system of the iron-free spectrometer will consist of 4 rectangular shape Si(Li) detectors placed along a focal plane so that it may accept L subshell lines simultaneously. A 2" x 2" NaI(Tl) spectrometer is temporarily being used as a movable counter. In the near future this scintillation counter is to be replaced by a multi-detector unit consisting of 4 Ge(Li) crystals. With this apparatus e⁻ - γ and γ-γ angular correlations can be measured simultaneously. A series of 10 single-channel analyzers select the pulse height of the movable counter. Singles counts and two-dimensional coincidence counts for each of four positions (altogether 10 x 10 x 4 bits of information) are stored in the magnetic core memory of a 400 channel pulse height analyzer. This electronics system has been made by Goulding and Landis.

Since the two fixed spectrometers select a gamma ray and the corresponding conversion electron lines with good resolution, the ratio of two angular correlation functions provides very good information on the
transition detected by the fixed detectors, that is,

\[ \frac{A_v^{(i)}(e^{-\Sigma}\gamma')}{A_v(\gamma-\Sigma\gamma')} = \frac{F_v^{(e_i)}}{F_v(\gamma)} \]

where \( i \) denotes an electron shell (K, L, etc). If the transition in question is of pure multipole order, then this quantity is a particle parameter itself. A project to determine particle parameters for not only K but also L subshell electrons is in progress.

The use of a Si(Li) detector makes it very easy to measure angular correlations involving K, L and M conversion electrons simultaneously. The significance of angular correlations involving L conversion electrons will be discussed in next sections.

III. SIGNIFICANCE OF L CONVERSION ELECTRONS IN ANGULAR CORRELATION

In earlier states of angular correlation experiments only K conversion electrons were involved. One of the reasons for this is that there were no theoretical particle parameters available for L conversion electrons. Another reason is the experimental situation which existed in the past. Now these circumstances seem being overcome. Actually, theoretical values have been published and are getting more and more available.

The advantage of the angular correlation using L conversion electrons is that it adds three (if subshell electrons are resolved) or at least one (if integrated L electrons are involved) more bits of information to \( e_K-\gamma \) and \( \gamma-\gamma \) angular correlations.
Let us take for example the case of a $2^+ (E_2 + M_1 + E_0) \rightarrow 0^+ (E_2)$ cascade. The $\gamma-\gamma$ angular correlation function is

$$A_2 (\gamma-\gamma, E_2 + M_1 + E_0) = \frac{1}{1 + \delta^2} \left[ A_2^e + 2\delta A_2 + \delta^2 A_2^m \right]$$

and $e-\gamma$ angular correlation function for each shell "i" is expressed as follows:

$$A_2 (i) (e-\gamma), E_2 + M_1 + E_0) = \frac{1}{1 + p_1^2 + q_i^2} \left[ b_2 (i) (E_2) A_2^e + 2p_1 b_2 (i) (M_1 - E_2) A_2 + p_1^2 b_2 (i) (M_1) A_2^m + q_i b_2 (i) (E_0 - E_2) \right],$$

where

$$q_i = \sqrt{\frac{\omega (i, Z, \lambda)}{\alpha_2 (i) W_\gamma (E_2)}} \rho,$$

$$p_1 = \sqrt{\frac{\beta (i)}{\alpha_2 (i)}} \delta.$$

Here $p_1$, $q_i$, $b_2 (i) (M_1 - E_2)$ and $b_2 (i) (M_1)$ are functions of the unknown parameters $\rho$, $E_0$ strength parameter), and $\delta$ and $\lambda$. As pointed out in Section I, $\alpha^K$, $A_2 (\gamma-\gamma)$ and $A_2 (e-\gamma)$ cannot determine these parameters uniquely. $A_2 (e-\gamma)$ and $\alpha^K$ will remove the ambiguity, because these quantities are independent of $A_2 (e-\gamma)$ and $\alpha^K$. For simplicity, let us assume that $p_1 << 1$ and $q_i << 1$. Then the sensitivity of $A_2 (i)$ to $\delta$ and $\rho$ is
expressed by

$$\frac{\partial A_2^{(i)}}{\partial \delta} = 2b_2^{(i)} (M_1 - E_2) A_2 \sqrt{\frac{\beta_1^{(i)}}{\alpha_1^{(i)}}},$$

$$\frac{\partial A_2^{(i)}}{\partial \rho} = b_2^{(i)} (E_0 - E_2) \sqrt{\frac{\Omega^{(i)}(z,k)}{\alpha_2^{(i)} W^{(E2)}}}.$$

For example, when $Z = 81$ and $k = 0.6$,

$$\frac{\partial A_2^{K_1}}{\partial \delta} = 0.377 \times 2A_2$$

$$\frac{\partial A_2^{L_1}}{\partial \delta} = 0.625 \times 2A_2$$

$$\frac{\partial A_2^{L_2}}{\partial \delta} = 0.370 \times 2A_2.$$

This example shows that $e^{-} L - \gamma$ angular correlation is quite promising.

IV. PRELIMINARY RESULTS ON THE ANGULAR CORRELATIONS IN Pt$^{196}$

For the purpose of showing the applicability of L conversion electrons, measurements on $^{333} \gamma - 356 K, L, M$ and $^{333} \gamma, L, M - 356 \gamma$ angular correlations in Pt$^{196}$ have been performed using the apparatus adopting a Si(Li) crystal, as described in Section II. The electron
spectrum of Au$^{196}$ taken with a 14 mmφ × 3 mm thick Si(Li) detector, singles and coincident with $333 + 356\ \gamma$, are presented in Fig. 3. Here the L peak involves all the L-subshell electrons and the M peak involves M, and higher-shell electrons. The obtained correlation functions are illustrated in Fig. 4, and uncorrected correlation functions are tabulated in Table 1.

Although this data is too preliminary to deduce a quantitative argument, they allow one to make qualitative discussions.

The $A_{i}^{(1)}(e-\gamma)$ coefficient itself does not give any information on the parameters $q$ and $\lambda$, since it depends only on the E2 component. However, from the relations

$$b_{i}^{(1)}(E2, 356) = \frac{A_{i}^{(1)}(333\ \gamma - 356\ e)}{A_{i}^{(1)}(333\ \gamma - 356\ \gamma)}$$

and

$$b_{i}^{(1)}(E2, 333) = \frac{1 + p_{1}^{2} + q_{1}^{2}}{1 + \lambda^{2}} \frac{A_{i}^{(1)}(333\ e - 356\ \gamma)}{A_{i}^{(1)}(333\ \gamma - 356\ \gamma)} \simeq \frac{A_{i}^{(1)}(333\ e - 356\ \gamma)}{A_{i}^{(1)}(333\ \gamma - 356\ \gamma)}$$

we can determine $b_{i}^{(1)}(E2)$ particle parameters. It is worth noting that the determination of $b_{i}^{(1)}(E2)$ parameter is a very sensitive way to determine $b_{2}^{(1)}(E2)$ parameter, because these two quantities are related by an equation

$$\frac{b_{i}^{(1)}(E2) - 1}{b_{2}^{(1)}(E2) - 1} = -2.5$$

and furthermore $A_{i}$ is less affected by the admixture of dipole or monopole component. The present data shows that the $333\ \gamma - 356\ K$ and $333\ K - 356\ \gamma$ angular correlations have small negative $A_{i}$ coefficients. This fact implies the $b_{2}^{K}(E2)$ for 333 keV or 356 keV is slightly larger than 1.4. In Fig. 5
are shown theoretical curves of E2 particle parameters calculated by
Biedenharn and Rose\textsuperscript{\ref{16}} (point nucleus) and by Band et al.\textsuperscript{\ref{15}} (finite-size
nucleus, screening). The experimental tendency seems to agree qualitatively
with the theoretical predictions. All the angular correlations involving
L and M conversions reveal considerable positive $A_4$ coefficients. This fact
shows that $b_4^L(E2)$ and $b_4^M(E2)$ have positive values. As for L conversion $S$
this fact seems to agree with theoretical prediction. It is seen that M
conversion electrons have nearly the same particle parameters as L
conversion electrons.

The angular correlation of L and M electrons is fairly different
from that of K electrons because of the difference not in $b_2(E2)$ but in
$b_4(E2)$, as demonstrated here experimentally and illustrated in Fig. 5
theoretically. Recently Sakai, Yamazaki and Ejiri\textsuperscript{\ref{17}} reported anomalous
experimental K/L ratios of E2 transitions emitted after (p,2n) reactions
and made arguments that the observed anomalies might be attributed partly
to angular distribution of gamma rays and consequently to different behavior
of K and L electrons due to the difference in particle parameter. The present
result shows that this phenomena is supposed to arise not only from the
$P_2(\cos \theta)$ term but also $P_4(\cos \theta)$ term of angular distribution.

Now we have two quantities, $A_2^K(e-\gamma)$ and $A_2^L(e-\gamma)$, which are
independently correlated to the nuclear-structure parameters $q$ and $\lambda$.
Although at the moment there is no numerical basis for analyzing this data,
they will be helpful in the near future.

The current project described here is in progress with the collabora-
tion of J. M. Hollander.
V. SPECIAL PROBLEM

Because of different angular correlations of gamma rays and conversion electrons the conversion coefficient of the second transition with respect to the first transition has an angular dependence:

\[
\alpha^{(1)}(\theta) = \tilde{\alpha}^{(1)} \sum_y A_y P_y (\cos \theta) = \tilde{\alpha}^{(1)} \sum_y A_y P_y (\cos \theta),
\]

where \( \tilde{\alpha}^{(1)} \) is the ordinary conversion coefficient observed when coincidence is not taken. The deviation depends not only on the nature of the second transition but on what kind of emission is involved in the first transition. Anyway, deviations of this type can be accounted for completely in terms of particle parameters. Now we may raise a question as to whether there is an anomaly of conversion coefficients which arises from the dynamical rearrangements of atomic configuration following the preceding transition. The following discussion is concerned with this problem.

Let us suppose a simple cascade of two gamma transitions. In Fig. 6 are illustrated intermediate atomic states following gamma rays and conversion electrons. For simplicity higher shells and the Auger effects are neglected. K conversion process produces a K electron hole, which proceeds to L_{II} and L_{III} electron holes with the emission of K_{\alpha_2} and K_{\alpha_1} X-rays, respectively. Similarly, L subshell conversion process produces an L subshell electron hole, while gamma rays produce no change in the inner atomic configuration. Then, the occupation probability of the "i" electron orbit has a time-dependent form.

\[
\xi_i(t) = 1 - a_i e^{-t/\tau_i},
\]
where $t$ = time elapsed after the first transition occurs,

$t_i$ = mean life time of the "$i$" electron hole,

$\alpha_i$ = vacancy probability of the "$i$" orbit at $t=0$.

The values of $a_{I,II,III}$ for various experimental conditions are presented in Table II.

Unless the mean life time of the intermediate nuclear state, $\tau_N$, is too long compared with $t_i$, reduction of the emission probability of conversion electrons should occur due to the lack of electrons in the shell in question. The conversion coefficient becomes anomalous as given by

$$\alpha^{(i)} (\theta, \text{static}) = \left[1 - \alpha_i \frac{t_i}{\tau_N} \frac{I_i}{\tau_N + t_i} \right] \alpha^{(i)} (\theta, \text{static})$$

where $\alpha^{(i)} (\theta, \text{static})$ means the conversion coefficient given by Eq. (1), which includes the angular correlation effect. The anomaly factor depends on $a_i$ and $\tau_i/\tau_N$, as illustrated in Fig. 7.

It is well known that $\tau_K$ is shorter than $10^{-16}$ sec for nuclei of $A \approx 50$, whereas $\tau_L$ is longer than $10^{-14}$ sec. Therefore there is no possibility of such an anomaly for K conversion electrons. On the other hand, $\tau_L$ can be so close to $\tau_N$ of a very fast transition that such an anomaly may be observed in some particular cases. There is no reliable experimental data on $\tau_{L_{I,II,III}}$, because it is too long to permit measurements of natural width of L X-ray lines. If we neglect the Auger process, which may not be valid for medium-weight nuclei, the single-particle approximation gives

$$\tau_i = \frac{1}{f_i} \cdot \frac{Z^2}{E_L} \times 10^{-6} \text{ sec},$$

where $E_L$ is the energy of L X-rays in eV, and $f_i$, defined by
\[ f_{i} \equiv \frac{\sum |\langle j \mid r \rangle_{i}|^2}{(a_0/z)^2}, \]

is a quantity of order of 1. For example, for \( Z = 50 \), \( f_{i} \zeta_{i} \) is \( 4 \times 10^{-14} \) sec.

A possible experimental method to detect the anomaly is, for example, to compare \( L_{I,II,III}/K \) ratios in coincidence with the preceding conversion electrons or K X-rays or gamma rays. In order to discriminate the anomaly, the complete knowledge of angular correlation functions involving conversion electrons is of essential importance.

It is worth pointing out that if we have reliable knowledge on \( \zeta_{i} \), this method will be a powerful tool to measure a very fast nuclear life time of order of \( 10^{-13} \) or \( 10^{-14} \) sec. The situation is similar to the measurement of monoenergetic positron line which is as well related to the lifetime of an electron hole. Actually, Wiener et al.\(^{19}\) determined the nuclear life time of the 1/20-keV transition in \(^{206}\)Pb to be \( 2.1 \times 10^{-14} \) sec by measuring the intensity of the monoenergetic positron line which was produced as a consequence of the capture of an electron of internal pair formation into the K electron hole following K electron capture. In this case, \( \zeta_{K} = 1.15 \times 10^{-17} \) and \( \zeta_{K}/\zeta_{N} \) is as small as \( 10^{-3} \). Comparing with this, we see that the present method has a shortcoming in that the quantity to be measured is proportional to \( 1 - \zeta_{i}/\zeta_{N} \) so that the small value of \( \zeta_{i}/\zeta_{N} \) is difficult to detect, whereas in the latter the quantity is proportional to \( \zeta_{i}/\zeta_{N} \).

The author would like to appreciate the discussions with Drs. J. M. Hollander, T. Novakov, J. O. Rasmussen, and M. Sakai.
