Abstract

Aberrant thyroid follicles have been found in the thymi of female Sprague-Dawley rats. The accumulation of $^{131}$I by such follicles, shown autoradiographically, indicated their functional nature.

In the course of a study on the long-term effects of massive doses of I\(^{131}\) in rats, aberrant thyroid tissue in the thymus was found in unexpectedly high incidence in the untreated controls. In 21 normal female rats of the Sprague-Dawley strain whose ages ranged from 260 to 427 days, one or more thyroid follicles were found in routine sections of thymus of eight rats. Cords or sheets of epithelium resembling that of the thyroid were found in an additional four rats; in these four there was no follicular arrangement or association with colloid. An attempt has been made to demonstrate whether or not the thyroid follicles in the thymus take up radioiodine and incorporate it in colloid.

Methods

Female rats of the Sprague-Dawley strain received 50 \(\mu\)c per gram of body weight of I\(^{131}\) when 55 days old and were autopsied 24 hours later. Histological sections were made of the thymus and autoradiographs were prepared on Eastman Kodak 10-\(\mu\) NTA stripping film.

Results

Figure 1 illustrates the thymus of one of the rats at low magnification; thyroid follicles may be seen in the medulla. The tissue surrounding these follicles is characteristic of the thymic medulla. At higher magnification (Fig. 2) it is seen that these follicles possess a cuboidal epithelium and are filled with colloid. The colloid variably appears deeply eosinophilic and homogeneous or pale-staining and vacuolated—the latter suggests resorption. The follicles also vary in autoradiographic density (Fig. 3), but all show some radioiodine concentration. Thus, in structure and in iodine concentration these follicles are like those found in the thyroid gland proper.

Discussion

The possibility that accessory thyroids and aberrant thyroid tissue may occur, especially in the mediastinum, has been long recognized. Adequate embryological explanations may be derived by study of the development of the branchial pouches, which are the anlagen of both thyroid and thymus. It has been shown that administration of thiourea to Wisbar strain rats resulted in a high incidence of thyroid adenomata in the thymus. The objective of this communication is to point out a relatively high incidence of accessory thyroid tissue in an animal commonly employed in endocrinological experiments, and to show that this aberrant tissue may be functional rather than merely rudimentary. The findings have a bearing on experiments in which total thyroid ablation is critical; surgical thyroidec-
tomy may not reach all the functional thyroid tissue, and may have to be followed routinely by radiiodine. It would, in fact, appear possible that following surgical thyroidectomy the resultant increase in pituitary output of thyrotropic hormone could stimulate aberrant thyroid tissue. This poss­ibility has been recognized, for example, in the studies by Entenman et al., in which surgical thyroidectomy was followed by hypophysectomy.

Critical studies are under way to compare the thymi of surgically thyroidectomized rats with those of rats in which thyroid ablation was accomplished by radiiodine. Already differences in the oxygen consum­ption in the two groups of rats have been demonstrated by metabolimetry.

This work was performed under the auspices of the U. S. Atomic Energy Commission and the Committee on Research, University of California.
