Summary

Biosensors detect signals using biological sensing components such as redox enzymes and biological cells. Although cellular versatility can be beneficial for different applications, limited stability and efficiency in signal transduction at electrode surfaces represent a challenge. Recent studies have shown that the Mtr electron conduit from *Shewanella oneidensis* MR-1 can be produced in exoelectrogenic *E. coli* to generate an exoelectrogenic model system with well-characterized genetic tools. However, means to specifically immobilize this organism at solid substrates as electroactive biofilms have not been tested previously. Here, we show that mannose-binding Fim pili can be produced in exoelectrogenic *E. coli* and can be used to selectively attach cells to a mannose-coated material. Importantly, cells expressing fim genes retained current production by the heterologous Mtr electron conduit. Our results demonstrate the versatility of the exoelectrogenic *E. coli* system and motivate future work that aims to produce patterned biofilms for bioelectronic devices that can respond to various biochemical signals.

Introduction

Extracellular electron transfer (EET) is a biochemical process during which electrons are transferred across the bacterial cell envelope (White et al., 2016). EET holds great potential for application in biosensing applications (Prévotau and Rabaey, 2017) where EET-performing cells represent an attractive alternative to less stable enzymes as sensing elements. Such biosensors contain the biological sensing element immobilized on a conductive surface where it performs the transduction of a specific chemical signal into an electric output. The capability of certain microbial species to reduce solid minerals at their surface allows their cultivation at the anode of a bioelectrochemical system (BES) and their genetic modification paved the way for their application in bioprocess and environmental monitoring (Webster et al., 2014; Prévotau and Rabaey, 2017). In sensing applications, EET is utilized as a signal transducing process that, although slower than enzyme catalysts, is attractive when longevity, production costs, electric connection of the biological component, sensitivity and simultaneous processing of several signals are important.

Three decades ago, EET was discovered as manganese and iron respiration in species of *Geobacter* and *Shewanella* (Lovley and Phillips, 1988; Lovley, 1991; Marsili et al., 2008a). More than 90 species have been reported to perform EET (Koch and Harnisch, 2017) including the EET model organisms *Geobacter sulfurreducens* and *Shewanella oneidensis*. Both species gain chemical energy in the form of ATP by coupling carbon oxidation to anaerobic reduction of metal oxide minerals such as Mn(III), Mn(IV), Fe(III), Cr(VI) and U(IV) in the

extracellular space (Richter et al., 2012). Despite the considerable number of reported electroactive microbes, the composition of their extracellular electron transfer pathway has remained largely unknown and is still limited to a small number of anode-respiring bacteria (Kracke et al., 2015). In S. oneidensis, EET is initiated at the inner cell membrane where electrons, originating from the oxidation of primary fermentation products (e.g. lactate, pyruvate, formate and hydrogen), are transferred to membrane-embedded menaquinols by formate and NADH dehydrogenases (Meshulam-Simon et al., 2007; Pinchuk et al., 2009; Cordova et al., 2011; Brutinel and Gralnick, 2012a; Kane et al., 2016). Menaquinol is in turn oxidized by the inner membrane-bound quinol dehydrogenase CymA (Marritt et al., 2012), or in its absence, the enzyme complex SirCD (Cordova et al., 2011). Next, electrons are transferred across the periplasmic space by diffusible c-cytochromes STC and FccA (Schuetz et al., 2009; Fonseca et al., 2013) and transferred to terminal reductases at the outer membrane such as MtrA and MtrC which are associated with the MtrCAB complex (Fig. 1) (Coursolle and Gralnick, 2010; Breuer et al., 2015). On the extracellular face of the outer membrane, MtrC accepts electrons from MtrA and transfers these charges either directly onto an insoluble electron acceptor or onto secreted flavin molecules (Brutinel and Gralnick, 2012b; Xu et al., 2016).

Several research groups have used current knowledge on extracellular respiration to engineer non-natural exoelectrogens by synthetic biology methods (TerAvest and Ajo-Franklin, 2016). Among these, the transfer of the EET capacity of S. oneidensis into the well-studied gene expression host E. coli has been explored in several studies (Pitts et al., 2003; Gescher et al., 2008; Jensen et al., 2010; Goldbeck et al., 2013; TerAvest et al., 2014; Sturm-Richter et al., 2015; Förster et al., 2017). One such EET system was developed recently by Jensen et al., who have incorporated the S. oneidensis inner membrane c-cytochrome CymA and the outer membrane complex MtrCAB into E. coli yielding the strain cymAmtrCAB (Jensen et al., 2016). Remarkably, this strain was able to transfer electrons across the cell envelope in the absence of the periplasmic S. oneidensis cytochromes STC and FccA. Since CymA can reduce MtrA in vitro (Firer-Sherwood et al., 2011), Jensen et al. proposed that the electrons transit the ~15 nm wide E. coli periplasm (Matias et al., 2003) by diffusion of periplasmic MtrA. Hence, the four S. oneidensis MR-1 proteins CymA and MtrCAB form a functional Mtr electron transfer pathway (METP) in E. coli and were employed in the present study as a membrane-bound electron conduit. Electroactive E. coli strains such as cymA-mtrCAB differ from naturally occurring electroactive species in that the currently available exoelectrogenic E. coli strains neither form cohesive biofilms on electrodes nor utilize efficient extracellular electron transport mediators such as conductive pili or flavins. When considering strict anaerobic exoelectrogenic species such as G. sulfurreducens, the oxygen tolerance of E. coli can be regarded as a desirable feature as it may facilitate its incorporation in novel type of bio-electronics that are usually handled under ambient conditions. In addition, the use of non-biofilm-forming cells in electrochemical biosensors is complicated by complex chemical or physical immobilization and, in the case of biofilm-forming species, low reproducibility, required initial growth time and limited strain availability have to be considered during sensor design (Prévot and Rabaei, 2017).

In order to further increase the relevance of the electroactive biological cell to bioelectronic applications, it is necessary to develop strains that can be stably and selectively immobilized at conductive substrates in situ. This may be done by, for instance, patterning of a biosensor surface with a synthetic biofilm consortium that can detect and process multiple signals in parallel. The attachment of current-producing bacteria on conductive surfaces was attempted previously using gold-binding peptides that were integrated with an E. coli outer membrane protein and displayed on the outer surface of S. oneidensis (Kane et al., 2013). This system failed to maintain current production while introducing binding and, thereby, no strategy is currently available for
achieving pattern with exoelectrogenic bacteria. The specific and strong attractive interactions that are required for such an attachment are naturally provided by rod-like carbohydrate-binding cell appendages called pili (Fig. 1). These protein structures are naturally produced by, for example, uropathogenic *E. coli* strains (Thomas *et al.*, 2004; Korea *et al.*, 2011) and are potentially useful additions to the exoelectrogenic *E. coli* strain because these appendices have naturally evolved to mediate attachment with low impact on other outer membrane functions. Here, we explore the possibility of obtaining an exoelectrogenic biofilm-forming *E. coli* variant by production of mannose specific Fim pil and report the effect of pili production on the cytochrome production levels, the exoelectrogenic performance and its adhesive properties with respect to Fim ligands and an electrode surface.

### Results and discussion

**Design of** *E. coli* **coproducing CymAMtrCAB and FimAICDFGH for the biochemical characterization of Fim pili and the METP**

In order to test whether functional Fim pil and the METP comprising the *S. oneidensis* electron transfer proteins CymA and MtrCAB can be coproduced in *E. coli*, a set of four *E. coli* strains was constructed (Table 1). This included a reference strain, called *cymA-mtr-SmR*\(^{\text{\textregistered}}\), which was prepared from the existing exoelectrogenic *E. coli* strain *cymA-mtr* (TerAvest *et al.*, 2014) by transformation with the insert-free expression vector pCDFDuet-1. In addition to pCDFDuet-1, this *E. coli* strain contained the vectors pEC86 and IS049, which are required for the efficient production of the *S. oneidensis* electron conduit in *E. coli*. The recombinantly expressed genes comprised the *E. coli* cytochrome c maturation genes *ccmA-H*, which were incorporated in the pEC86 construct under the control of the constitutive tet promoter. The *cymAmtr-CAB* gene cluster was placed downstream of the IPTG-inducible T7/lac promoter in the plasmid IS049. Three additional *E. coli* strains were prepared in order to investigate whether functional Fim pil can be produced in the studied *E. coli* system and distinguished from the non-piliated phenotype. These strains were designed to either coproduce Fim pil and CymAMtrCAB (strain *cymA-mtr-fim*), to exclusively produce Fim pil as heterologous membrane protein (strain *fim-Kan*\(^{\text{\textregistered}}\)) or not to produce any heterologous cell envelope proteins at all (strain Kan\(^{\text{\textregistered}}\)-SmR\(^{\text{\textregistered}}\)). All these strains carried three different plasmids of which the *ccmA-H* expression construct pEC86 was included in every strain. In addition, Kan\(^{\text{\textregistered}}\)-control strains Kan\(^{\text{\textregistered}}\)-SmR\(^{\text{\textregistered}}\) and *fim-Kan*\(^{\text{\textregistered}}\) contained the empty pET30a+ derivative pSB1ET2 while the strains *cymA-mtr-SmR*\(^{\text{\textregistered}}\) and *cymA-mtr-fim* carried the pSB1ET2 derivative IS049 with added *cymAmtrCAB* gene insert under the control of the T7/lac promoter. Non-piliated control strains (SmR\(^{\text{\textregistered}}\)) harboured the insert-free expression construct pCDFDuet-1 and piliated *fim* strains contained the pCDFDuet-1 derivative pMiI20. This plasmid included the Fim pil gene cluster *fimAICDFGH* inserted downstream of the IPTG-inducible T7/lac promoter.

**Recombinant Fim pili production attenuates CymA concentration but imposes little stress on exoelectrogenic *E. coli***

The heterologous production of recombinant outer membrane proteins in the host *S. oneidensis* has been reported to adversely affect the production of the outer membrane protein complex MtrCAB (Kane *et al.*, 2013). To test whether this is also true in the case of added Fim pil in the exoelectrogenic *E. coli* strains, we cultivated the four *E. coli* strains Kan\(^{\text{\textregistered}}\)-SmR\(^{\text{\textregistered}}\), *fim-Kan*\(^{\text{\textregistered}}\), *cymA-mtr-SmR*\(^{\text{\textregistered}}\) and *cymA-mtr-fim* in BES’s under anaerobic conditions overnight at a working electrode potential of +200 mV versus Ag/AgCl. Samples were taken from the BES and analysed with regard to the cell content of type I pili components using immunoblotting (FimCH) and electron transfer proteins using enhanced chemiluminescence (CymA, MtrA and MtrC). A comparison of the FimC and FimH production levels in the whole cell lysates of two *fim* strains revealed that intensity of both proteins was lower when the METP genes were coexpressed (Fig. 2A). Similarly, analysis of the *c* type cytochromes revealed that CymA levels were clearly decreased while MtrC and MtrA levels were largely unchanged when compared to the strain lacking the *fim* gene cluster (Fig. 2B). We speculate that the decrease in relative expression levels is due to a limited overall production capacity for membrane proteins. The stress imposed on the exoelectrogenic *E. coli* cell by

recombinantly produced pili and electron transfer proteins was monitored through the rate of growth at 37°C. These experiments showed that there was no measurable difference in growth rate between the control strain KanR-SmR and the Fim pili gene expressing strain fim-KanR (Appendix S1). In the presence of cytochrome genes, a 20% decreased growth rate was measured when compared to the E. coli strains lacking the METP genes. These data indicate that the production of the S. oneidensis electron transfer components is a larger energetic burden to the E. coli cell than the production of E. coli Fim pili.

**Fim gene expression increases binding to mannose-coated surfaces**

The mannose specific binding of the E. coli strains was studied as adsorption to mannose-functionalized agarose beads. Microscopy images reveal attached cells in the case of fim strains as apparent for strain fim-KanR (Fig. 3A and B). The variant cymA-mtr-fim formed slightly less dense cell layers, while almost no attachment of cells was observed in the case of the non-piliated control strains KanR-SmR and cymA-mtr-SmR (Fig. 3C). These experiments showed that mannose-binding Fim pili can be produced in the exoelectrogenic E. coli system and that the two E. coli fim strains form biofilms on mannose with no significant background binding.

![Fig. 2](image-url)  
**Fig. 2.** Analysis of recombinant protein levels in E. coli strains using SDS-PAGE (4–20% polyacrylamide gradient) and Western blot analysis. The analysed cell lysates were prepared from strains that either did not contain S. oneidensis EET components or pili genes (KanR-SmR), the Fim pili gene cluster fimAICDFGH but no encoded S. oneidensis EET components (fim-KanR), no Fim pili genes but the S. oneidensis EET component gene cluster cymAmtrCAB (cymA-mtr-SmR) or both, pili and S. oneidensis EET component gene clusters (cymA-mtr-fim). The cells were collected following an overnight incubation in a BES at a EWE of +200 mV versus Ag/AgCl. The separated cell lysates were labelled with rabbit antibodies specific for Fim pili components FimC and FimH (A). Bound antibodies were visualized by enhanced chemiluminescence following addition of horseradish peroxidase-conjugated secondary antibodies (A). In subfigure B, redox-active cytochromes CymA, MtrA and MtrC were detected directly by enhanced chemiluminescence. The positions of molecular weight standard proteins, the predicted positions of the antibody labelled proteins (A) and haem-containing proteins (B) along with their molecular weights are indicated.

The capacity of the METP to reduce soluble substrates is preserved during pili coproduction

The effect of pili coproduction on the Mtr electron transfer functionality was measured using a soluble Fe(III) reduction assay. This was done using cells of all four E. coli strains that were, prior to this reduction assay, incubated overnight in an anaerobic BES at a working electrode potential of +200 mV versus Ag/AgCl. The observed Fe(II) formation indicated that the two cymAmtr strains were performing the Fe(III) reduction at identical rates that were significantly above the apparent background reduction activity as measured in M1 medium (Fig. 4). The Fe(III)-reductive activity of both KanR-control strains was identical to the background activity, which confirmed that this assay specifically measures the activity of the METP. Based on the differential CymA production (Fig. 2B), the unchanged ferric citrate reduction rate of cymA-mtr-fim when compared to the non-piliated strain cymA-mtr-SmR is an unexpected result. The apparent tolerance of the exoelectrogenic E. coli to decreased CymA levels may be due to the presence of the native inner membrane cytochrome NapC which has been proposed to fulfill the same EET function as CymA (Jensen et al., 2016). These data suggest that Fim pili and the METP can be coproduced without affecting the capability of the cell to reduce soluble electron acceptors.
E. coli producing type 1 pili and the METP produce current and show increased persistence in BESs

Lactate cannot be fermented by E. coli and was therefore chosen as a substrate to test the ability of the cell to transfer electrons released from substrate oxidation to an extracellular electrode. The current response was monitored by chronoamperometry for at least 50 h following addition of lactate [40 mM]. The initial lactate concentration was chosen based on previous studies in which the exoelectrogenic E. coli system produced a clear electric signal under similar conditions (TerAvest et al., 2014). The cytochrome-free strains fim-KanR and KanR-SmR produced constant currents throughout the measured interval with current densities of 0.70 ± 0.08 and 1.09 ± 0.07 μA cm⁻² respectively (Fig. 5). Those background currents may be related to hydroquinone derivatives that have previously been proposed to be produced by E. coli cells and which may act as mediators of extracellular electron transport (Qiao et al., 2011). The highest electroactivity was measured with the cytochrome producing strain cymA-mtr-SmR that started with a current density of 3.6 μA cm⁻² followed by a steady increase to a maximum current density of 4.5 μA cm⁻² over a 28 h period after which the current decreased to 4.0 μA cm⁻² by the end of the experiment. The current density produced by the strain which coproduced pili and cytochromes increased from 1.8 μA cm⁻² to a maximum of 1.9 μA cm⁻² during 20 h and decreased to a level of 1.7 μA cm⁻² at 55 h past lactate addition. Monitoring of the lactate concentration by HPLC analysis showed that all tested strains consumed only a small fraction of the added lactate substrate during the electrocultivation, which is consistent with predictions based on the observed electric currents and showed that the availability of this substrate was not limiting metabolic activity. The current produced by strain cymA-mtr-fim was significantly higher than the current of 1.07 μA cm⁻² monitored by chronoamperometry for at least 50 h following addition of lactate [40 mM].
that was measured with the most electroactive non-Mtr control strain KanR-SmR (Fig. 5, Appendix S2; \( P = 0.018 \); two-tailed Student’s \( t \)-test).

Interestingly, the current produced by \( E. coli \) cymA-mtr-fim was 58% lower than the electric current measured with the non-piliated form (i.e. \( \text{cymA-mtr-Sm}^R \); 4.0 \( \mu \text{A cm}^{-2} \)). The ferric citrate reduction assay has shown that this current decrease is not due to a METP disruption. We speculate that this effect is due to steric restrictions of attractive electrode–cell interactions that are imposed by Fim pili and lead to a reduction in outer membrane cytochromes (such as MtrC) that are close enough to the electrode surface to participate in direct electron transfer. This hypothesis is supported by the observation that cell suspensions of both \( \text{fim} \) strains do not sediment upon static incubation at room temperature whereas both SmR strains settle out of the fluid under these conditions (data not shown). A similar phenomenon has been reported by Meuskens et al. (2017) who have observed increased flocculation of \( E. coli \) strains which lacked several outer membrane proteins. As an explanation, the authors proposed a shielding function of outer membrane proteins that controls aggregation by limiting electrostatic attraction between cells. Such charge shielding may also limit electron transfer to the carbon electrode in the exoelectrogenic \( E. coli \) system but does, as is apparent from the unchanged ferric iron reduction, not affect the electron transfer to soluble electron acceptors. The small size of the ferric iron anion may allow it to penetrate the pili layer and support EET in pili-producing cells at the same rate as in non-piliated cells. The shielding effects of pili may be mitigated by usage of a more tunable induction system for pili gene expression.

Exoelectrogenic \( E. coli \) cells spontaneously adsorb to carbon electrodes as thin layers and since type I pili promote the aggregation of \( E. coli \) cells (Ogden and Taylor, 1991), we hypothesized that the thickness of a spontaneously adsorbed exoelectrogenic biofilm could be increased by expression of \( \text{fim} \) genes. To test this, we measured the biomass present in solution and on the anode surface after 5 days in the BESs. Examination of anode-bound biomass and biomass in solution shows that, while there are no significant differences in the solution biomass among the different strains, there is a significant -2.5-fold increase in anode-bound biomass in the \( \text{cymA-mtr-fim} \) strain relative to the strains KanR-SmR and \( \text{fim-Kan}^R \) (10.28 ± 1.66 mg versus 3.69 ± 0.50 mg and 3.31 ± 0.21 mg, \( P = 0.003 \) and 0.002, respectively; two-tailed Student’s \( t \)-test; comparison presented in Appendix S2). This observation indicates that, unlike adhesion to mannose-coated surfaces, \( \text{fim} \) expression alone was insufficient to significantly increase cell biomass on the anode. Rather, both Fim pili and the METP were required to enhance cell binding to the anode.

The exact mechanism through which the METP promotes cell adhesion is not evident from the presented data but may be linked to the cellular anodic respiration, which can only occur while the bacterial cell is in contact with the electrode. The KanR strains exhibited 40% background adsorption to carbon cloth, whereas no significant background adhesion was measured with the strains \( \text{cymA-mtr-Sm}^R \) and \( \text{Kan}^R \text{-Sm}^R \) on mannose. This indicates that utilization of Fim pili based carbohydrate binding for immobilization of exoelectrogenic cells is preferable over cytochrome mediated adsorption to carbon and a promising approach to achieve specific binding at solid surfaces. For this approach, the carbon electrode has to be modified with mannose groups which has been achieved previously by carbodiimide coupling of amino-functionalized mannose to a carboxylated carbon electrode substrate (Gu et al., 2008; Ehler et al., 2011). Carbohydrates may also be immobilized on gold (He et al., 2011), which, based on its low resistance and inertness, appears as an interesting alternative to carbon in biosensing applications. However, gold is prone to spontaneous protein adsorption (De Paoli Lacerda et al., 2010), which may prevent specific cell adhesion and external electron transfer.

**Fig. 5.** Chronoamperometry analysis of \( E. coli \) strains KanR-SmR, \( \text{fim-Kan}^R \), \( \text{cymA-mtr-Sm}^R \) and \( \text{cymA-mtr-fim} \) interacting with a carbon cloth working electrode poised at \( E_{\text{WE}} = +200 \text{ mV versus Ag/AgCl} \). Lactate was added at \( t = 0 \) h to a final concentration of 40 mM following an 18-h precultivation without carbon source. Error bars indicate standard error of triplicate measurements.

Coproduction of the METP and cell adhesion proteins in \( E. coli \) offers new opportunities for bioelectronic applications

The presented exoelectrogenic \( E. coli \) strain may be developed further for bioelectronic applications that
demand both, specific surface binding and higher EET rate by introduction of genetic modifications that result in a lower pili density and thereby improve the electron transfer through the extracellular space. Furthermore, the EET efficiency of this strain could be improved by utilization of the currently known conductive pili (Holmes et al., 2016) by, for instance, coproduction of conductive and adhesive pili in the same cell or by replacing the Fim pili with novel rationally designed hybrid pili that consist of a long conductive fibre and a terminal carbohydrate-binding adhesin. Alternatively, the EET of E. coli cymA-mtr-fim could be promoted through penetration of the pili layer with electrode-tethered conductive polymers such as linear naphtoquinone-modified polyethyleneimine hydrogels through which electrons can be transferred by shuttling between the covalently bound redox centres (Milton et al., 2015).

Among the selective cell adhesion systems found in nature, the adhesin/lectin–carbohydrate system is most common and includes a wide range of ligand–receptor pairs. In addition to this approach, other strategies have been employed, like, for example, biofilm patterning with a genetically engineered E. coli strain that adsorbs to various substrates with Ag43 adhesin upon illumination (Jin and Riedel-Kruse, 2018). The Ag43 adhesin system is, however, considered disadvantageous for the proposed signal multiplexing because it is non-specific and therefore incompatible with selective binding of different types of cells from a mixture. Other cell adhesion systems with technical relevance include, the cell binding by cell-surface bound antibody targets (Suo et al., 2008) and recombination of protein dimer components exposed at the outer cell membrane and the adhesion substrate (Chen and Wegner, 2017).

Existing electroactive biosensing applications, relevant for the exoelectrogenic E. coli system, include predominantly multispecies systems that were designed for monitoring of process parameters such as the oxygen demand, the production of volatile fatty acids and presence of toxins (Modin and Aulenta, 2007). In addition, several single-species sensing systems have been developed for, for example, monitoring of acetate by G. sulfurreducens (Tront et al., 2008; Nevin et al., 2011), sensing of lactate, fumarate and arabinose by S. oneidensis (Kouzuma et al., 2012; Gollitsch et al., 2013; Si et al., 2015) and the detection of arsenic by Enterobacter cloacae and S. oneidensis (Webster et al., 2014; Rasmussen and Minteer, 2015). More advanced applications include the cell-internal processing of quorum sensing signals which has been achieved by the creation of AND logic gates in S. oneidensis and P. aeruginosa (Li et al., 2011; Hu et al., 2015). The performance of biosensors will benefit from miniaturization, for example, sensing in microfluidic systems. The coproduction of METP and adhesive pili is a novel strategy with which electroactive cells can be targeted to inorganic surfaces and is therefore a promising approach for the realization of such patterned bioelectronics.

**Experimental procedures**

**Strains and plasmids**

Information on the plasmids, bacterial strains and primers used in this study is given in Table 1 and Appendix S3–S5. The plasmid pMil20 for recombinant Fim pili production was constructed by subcloning the fim operon as two PCR fragments from pSH2 (courtesy of Prof. Paul Omdorff) (Omdorff and Falkow, 1984). The fimAICD gene fragment was amplified and extended with a 5′-terminal restriction site using the PCR primers Ndel_fim-fw1 and SH2_27_rv. The fimDFGH gene fragment was amplified with a 3′-terminal Avrl restriction site using the primers SH2_24_hw and AvrII_fimH_rv1. Both fragments were cloned into pCR2.1-TOPO vectors (fimAICD: pCR2.1-TOPO+PCR4-c6; fimDFGH: pCR2.1-TOPO+PCR5-c6) using the TOPO TA cloning kit (Thermo Fisher Scientific, Waltham, MA, USA) and confirmed by sequencing. The vectors pCR2.1-TOPO+PCR4-c6 and pCR2.1-TOPO+PCR5-c6 were subjected to Ndel–BamHI and BamHI–AvrII digest to yield fimAICD and fimDFGH fragments respectively. The vector pCDFDuet-1 was double-digested using restriction enzymes Ndel and AvrII, and the resulting large vector fragment was ligated with the purified fimAICD and fimDFGH fragments yielding the expression construct pMil20 (Appendix S3 and S4). The correct assembly was confirmed by sequencing. An E. coli XL-1 Blue strain harbouring the plasmid pMil20 was deposited with the VTT Culture Collection (strain ID E-183557) as well as the presented E. coli C43(DE3) strain variants KanR-SmR (strain ID E-183553), fim-KanR (strain ID E-183555), cymA-mtr-SmR (strain ID E-183554) and cymA-mtr-fim (strain ID E-183566) (see Table 1).

**Culture conditions**

Prior to BES cultivation, bacterial cells were grown overnight at 37°C and 220 rpm in 5 ml 2×YT broth (16 g l⁻¹ tryptone, 10 g l⁻¹ yeast extract, 5 g l⁻¹ NaCl, pH 7.0, supplemented with 50 μg ml⁻¹ kanamycin, 100 μg ml⁻¹ chloramphenicol and 50 μg ml⁻¹ streptomycin). Then, 500 μl preculture was added to 50 ml 2×YT broth and incubated at 30°C and 220 rpm until an OD₅₉₅ₙₐ₅₉₅ nm of 0.5–0.9 was reached. The inducer isopropyl β-D-1-thiogalactopyranoside (IPTG) was then added to a final concentration of 50 μM. The production of recombinant proteins was allowed for about 20 h at a reduced agitation of 200 rpm. Cell cultures harbouring the IS049
vector were supplemented with the haem precursor δ-aminolevulinic acid at a final concentration of 1 mM in order to enhance haem biosynthesis and optimal cytochrome production (Fernandes et al., 2008).

**Detection of Fim pili component and cytochrome production by Western blot analysis**

Frozen E. coli cell samples were thawed and resuspended in B-PER bacterial protein extraction reagent (Thermo Fisher Scientific) at an OD_{595} nm of 3.5. The following components were added at the given final concentrations: 1.0 mM EDTA, 4.2 mM MgCl$_2$, 12 μg ml$^{-1}$ chicken egg lysozyme, 10 μg ml$^{-1}$ DNase I and 1.0 mM PMSF. The lysis reaction was performed at room temperature for 1 h followed by separation of the protein components in the lysed sample by reducing (analysis of Fim pili components) or non-reducing (analysis of cytochromes) SDS-PAGE (4–20% polyacrylamide gradient). The separated proteins were blotted onto nitrocellulose. Pili components FimC and FimH were labelled with a FimCH specific rabbit primary antibody (courtesy of David G. Thanassi) at a working dilution of 1:50 000. Primary antibody binding was detected by enhanced chemiluminescence using a rabbit-IgG-(H+L) specific antibody that was conjugated to horseradish peroxidase (Rockland Immunochemicals, Limerick, PA, USA) and reacted with SuperSignal West Pico chemiluminescent substrate (Thermo Fisher Scientific). The cytochrome detection was carried out by exposing the nitrocellullose membrane directly to the chemiluminescent substrate as previously described by Vargas et al. (1993).

**Mannose-binding assay**

Functional Fim pili production was monitored using a mannose-binding assay. E. coli cultures in which recombinant gene transcription was induced with IPTG (see above) were collected by centrifugation (15 min at 4°C and 3200 g) and resuspended in M1 medium (see Appendix S6). δ-mannose-coated agarose beads (Ø = 52–165 μm; bioWORLD, Dublin, OH, USA) were washed twice with ddH$_2$O and thrice with M1 medium (seven bead volumes, each). Washed beads (V = 5.5 μl) were combined with the cell suspension in microtite plate wells and diluted with M1 medium to OD$_{595}$ nm = 0.2 (V$_{Total}$ = 200 μl per well). The plate was sealed and incubated for 1 h at 37°C followed by sedimentation of the beads for 5 min at 22°C and 400 g. The supernatant was replaced with sterile M1 medium and the plate was incubated overnight at 22°C. Bacterial cells were fluorescently stained by addition of 0.3 μl propidium iodide solution (20 mM in DMSO) to each microtite plate well and a 15-min incubation at 22°C in the dark. The reaction liquid was replaced with M1 medium and cell binding examined at λ$_{EX}$ = 520–550 nm using an IX81 inverted microscope (Olympus, Tokyo, Japan).

**Soluble Fe(III) reduction assay**

All preparative steps of this method were performed in an anaerobic cabinet (80% N$_2$, 10% CO$_2$, 10% H$_2$). Cells suspended in M1 medium containing lactate [40 mM] were diluted to OD$_{595}$ nm = 0.5 using the same medium. Fe(III) citrate was added to the cells at a final concentration of 10 mM and the Fe(II) concentration was monitored by daily sampling. Fe(II) in 50 μl aliquots was acid extracted for 1 h in 0.5 mL 0.5 M HCl. The Fe(II) concentration was determined using a modified method from L. Stookey (Stookey, 1970) according to which 50 μl of the acid extract was added to 1.0 mL ferrozine solution (c = 1.0 M; dissolved in 0.1 M HEPES, pH 8.0) and left to react for 10 min. The concentration of the Fe(II)–(ferrozine)$_3^{2+}$ complex was determined from A$_{563}$ nm (k$_{563}$ nm = 27.9 mM$^{-1}$ cm$^{-1}$) of 200-μl reaction volumes using a Varioskan microtite plate reader (Thermo Fisher Scientific).

**BES setup**

The voltammetry cells were assembled according to the setup described earlier by Marsili et al. (2008b) with slight modifications. In detail, the setup comprised a 6.4-cm$^2$-sized rectangular carbon cloth working electrode (Panex 30–SW08; Zoltek, Nyergesújfalú, Hungary) which was cleaned by incubation in 1 M NaOH, 1 M HCl, acetone (2×) and ddH$_2$O (2×) and attached to a custom-made polyether ether ketone barrel (Ø = 9 mm) using Pt wire (Ø = 0.05 mm). The cell lid was manufactured in-house from Teflon, and the remaining components were purchased from Bioanalytical systems (West Lafayette, IN, USA) including a MR-1194 voltammetry cell, a MW-4130 Pt wire counter electrode (Ø = 0.05 mm) and an MF-2079 Ag/AgCl reference electrode that was contained in a MF-2031 glass chamber, capped with a MF-2064 Vycor frit and filled with 0.1 M NaCl. The assembled BES was sterilized by autoclaving without the Ag/AgCl reference electrode. After growth, the IPTG-induced cells were collected by centrifugation (2450 g, 15 min, 4°C) and washed three times in 20 mL ice-cold M1 medium. The cells were resuspended in 10 mL and diluted to OD$_{595}$ nm = 1.0 in a final volume of 60 mL using M1 medium as diluent. The remaining cells were collected by centrifugation (2450 g, 15 min, 4°C) and stored as a frozen pellet for Western blot analysis. For electrochemical measurements, 60 mL cell suspension was transferred into each BES, stirred at 200 rpm, maintained at 30°C and sparged with a humidified anoxic. 

atmosphere (80% N₂, 20% CO₂) at a flow rate of 5 ml min⁻¹.

**Electrochemical measurements**

Chronoamperometry experiments were executed using a WaveNow potentiostat (Pine Research Instrumentation, Durham, NC, USA).
