Beta-delayed proton decays of the nuclides $^{27}$P and $^{31}$Cl were measured using the helium-jet recoil collection technique and low-energy particle identification detector telescopes. In $^{27}$P, two new proton groups at $466 \pm 3$ keV and $612 \pm 2$ keV, with intensities of $9 \pm 2\%$ and $97 \pm 3\%$ relative to the main (100\%) group at $731 \pm 2$ keV, were discovered. Additionally, during the $^{27}$P experiments, a new proton transition was identified following the $\beta$-decay of $^{28}$P. This group, at a proton energy of $1452 \pm 4$ keV, had a $2 \pm 1\%$ intensity relative to the 100\% group at $679 \pm 1$ keV. A total $^{27}$P beta-delayed proton branch of $0.07\%$ was estimated. The experimental Gamow-Teller beta-decay strengths of the observed transitions from $^{27}$P was compared to results from shell model calculations. A search for new proton transitions in $^{31}$Cl, the next member of this $A = 4n+3$, $T_z = -3/2$ series, was unsuccessful. However, several proton peaks that had been previously assigned to $^{31}$Cl decay were shown to be from the decay of $^{25}$Si.

I. INTRODUCTION

The experimental investigation of the decays of proton-rich light nuclei has provided a wealth of spectroscopic information. This includes details of energy levels, spins, isospins, masses, half-lives and other decay properties. In light nuclei, total beta decay energies rapidly increase as one moves away from the valley of beta-stable nuclides towards the proton drip line. This opens up decay modes, such as beta-delayed proton and beta-delayed alpha emission, which are very sensitive probes of nuclear structure. There have been several recent articles that review the decay properties of proton drip-line nuclei [1-4].

The beta decays of proton-rich light nuclei (with $T_z \leq -1/2$) are characterized by two general features. The first is a fast superallowed Fermi transition to the isobaric analog state (IAS) in the beta daughter. If the IAS is above the proton separation energy, the beta-decaying precursor nuclide is classified as a strong beta-delayed proton emitter. The $A=4n+1$, $T_z=-3/2$ series of nuclei from $^{17}\text{Ne}$ to $^{73}\text{Sr}$ [3, 5, 6] (with the exception of the unobserved member $^{69}\text{Kr}$), are all strong $\beta p$ emitters. In contrast, the $A=4n$, $T_z=-1$ series of nuclei [3], from $^{24}\text{Al}$ [7] to $^{48}\text{Mn}$ [8] are designated as weak $\beta p$ emitters since the IAS in the beta daughters is bound with respect to proton emission.

The second $\beta$-decay feature consists of Gamow-Teller (GT) transitions to multiple states both below and above the IAS. Many of the lower lying states are bound with respect to proton emission and hence can only be examined through $\beta y$ studies. However, the states above the IAS are often open to proton emission. This cluster of states represents the tail of the Gamow-Teller giant resonance that has been observed in $(p,n)$ reactions [9, 10]. The experimental investigation of Gamow-Teller beta decay is an important means to study details of nuclear structure. The relatively restrictive nature of the Gamow-Teller transition operator, which flips both spin and isospin, implies that values of the GT matrix elements can be clearly related to specific properties of nuclear wavefunctions. The GT strength is typically centered around an excitation energy in the beta daughter that corresponds to the spin-orbit splitting.

The decays of the $A=4n+3$, $T_z=-3/2$ series nuclei, $^{27}\text{P}$ and $^{31}\text{Cl}$, with their large beta-decay Q-values, $(Q_{EC}(^{27}\text{P}) = 11.6 \text{ MeV}$ and $Q_{EC}(^{31}\text{Cl}) = 12.0 \text{ MeV}$) offer an opportunity to study GT transition strengths up to high excitation energies. The known members of this series in the sd-shell, $^{23}\text{Al}$ [11, 12], $^{27}\text{P}$ [13], $^{31}\text{Cl}$ [13-15] and $^{35}\text{K}$ [16], all exhibit beta-delayed proton branches. Since $\beta p$ studies of $^{23}\text{Al}$ have been recently reported by us [11], we concentrate here on $^{27}\text{P}$ and $^{31}\text{Cl}$ decays.

In the most recent (and most extensive) experimental investigation of the decays of $^{27}\text{P}$ ($T_{1/2} = 260 \pm 80 \text{ ms}$) and $^{31}\text{Cl}$ ($T_{1/2} = 150 \pm 25 \text{ ms}$) [13], only protons between 700 keV and 2700 keV could be observed with a detector resolution of 75 keV for. Utilizing our charged-particle detector telescopes, which can detect and identify low-energy protons with $\sim 30 \text{ keV}$
resolution, we undertook a study to improve upon our earlier results by searching for additional beta-delayed proton groups.

In that previous study [13], a full basis sd-shell model calculation was used to generate values of the Gamow-Teller strength [17] for all possible beta decay transitions of $^{27}$P and $^{31}$Cl. These shell model calculations [18-20] predict that a significant fraction of beta decay transitions should populate the states that make up the tail of the GT giant resonance; the study of $^{27}$P and $^{31}$Cl with their large beta decay energies are excellent candidate nuclei for sampling more of the GT resonance.

II. EXPERIMENTAL

Proton beams with energies of 28 MeV and 45 MeV from the 88-Inch Cyclotron at the Lawrence Berkeley National Laboratory were used to bombard five adjacent target foils of either 6 mg/cm$^2$ natural silicon (self-supporting) or 2 mg/cm$^2$ zinc sulfide (mounted on 1.7 mg/cm$^2$ of aluminum) to generate the radioactive nuclide of interest. Depicted in Fig. 1 is a schematic of the experimental setup, which employed the helium-jet transport technique (see, e.g., Ref. [5]) and charged-particle detector telescopes. Radioactive nuclei recoiled out of the target, were thermalized in the helium and were transported on potassium chloride aerosols along short 1 mm i.d. capillaries to a common header. They were subsequently transported along an 1.8 m long x 1.5 mm i.d. capillary and deposited onto the edge of a collector wheel. The total transit time was estimated to be 200 ms based on prior measurements. Two low energy gas $\Delta E$-gas $\Delta E$-silicon E detector telescopes, each subtending a solid angle of 3.5% of $4\pi$, viewed the deposition spot. The wheel was slowly rotated to reduce the buildup of longer-lived radionuclides.

A schematic cross sectional view of one of these detector telescopes is shown in Fig. 2. It consists of two $\sim 30$ $\mu$g/cm$^2$ CF$_4$ gas regions, which serve as $\Delta E$ detectors, followed by a 300 $\mu$m silicon E counter. This telescope is capable of identifying low-energy protons in extremely high-background environments of beta and alpha particles. The lower limit for particle identification is determined by the polypropylene entrance window, gas thicknesses, and the silicon detector deadlayer, as well as the electronics threshold, which were defined at the beginning of each experiment. For these measurements, the proton detection threshold was $\sim 240$ keV, while it was $\sim 550$ keV for alpha particles. Details of these detector telescopes are provided elsewhere [21, 22].

Detector calibrations were performed in situ with beta-delayed protons from the well-known [23, 24] $^{25}$Si emitter, $^{25}$Si, produced via the $^{24}$Mg($^3$He,2n)$^{25}$Si reaction at $E(^3$He) = 40 MeV, or through the $^{27}$Al(p,3n)$^{25}$Si reaction at $E(p) = 45$ MeV. In the case of $^{27}$P, additional proton calibrants came from the known [24, 25] beta-delayed protons of $^{28}$P, which was produced during both 28 MeV and 45 MeV proton bombardments on nat Si targets. All calibrations were conducted immediately before, or concurrently with, the main production run.
Figure 3 shows a $^{25}$Si beta-delayed proton spectrum recorded during the calibration phase. The typical detector resolution was 30 keV for protons, while it was 65 keV for alpha particles due to greater energy straggling in the detector components prior to reaching the Si detector.

Prompt neutrons can impinge on hydrogen-containing materials in or near the detector and produce protons that are indistinguishable from decay protons. To avoid detection of this "knockout" proton background, the cyclotron beam was pulsed and the counting electronics were enabled only during the beam off phase. The pulsing structure was chosen based on both the estimated He-jet transit time and on the half-life of the radioactive nuclide of interest. Based on the $260 \pm 80$ ms and $270.3 \pm 0.5$ ms half-lives of $^{27}$P and $^{28}$P, respectively, and the 200 ms He-jet transit time, a total cycle that consisted of 500 ms beam on phase followed by a 400 ms counting phase was used during the proton + silicon bombardments. Similarly, a pulsing structure that consisted of a 330 ms beam on phase followed by a 410 ms counting phase was selected during the proton + ZnS experiments to maximize the yield of $^{31}$Cl ($150 \pm 25$ ms). The proton beam current was limited to 2-3 $\mu$A on target in order to keep the count rate in the silicon counters below 50 kHz during the counting phase. This high count rate was due to the $\beta$-flux from the decays of nuclei closer to beta stability that were simultaneously and copiously produced.

III. RESULTS

A. Protons + Silicon Bombardments

Two proton beam energies were used to bombard targets of $^{nat}$Si. At 45 MeV, both $^{27}$P and $^{28}$P were produced, while at 28 MeV, chosen to be below the $^{27}$P production threshold of 30.7 MeV, the beta-delayed proton spectrum resulted solely from $^{28}$P. A comparison of the two spectra allowed the identification of the $^{27}$P $p\beta$ groups.

The spectrum of beta-delayed protons recorded during the 28 MeV bombardment on $^{nat}$Si targets is presented in Fig. 4. The integrated proton beam on target was 290 mC. The observed proton groups, labeled $p_1\ldots p_7$, all resulted from the beta-delayed proton decay of $^{28}$P, which was produced through the $^{28}$Si($p,n)^{28}$P reaction. Proton peaks $p_1\ldots p_6$, correspond to those previously observed [25], while proton group $p_7$, at $1452 \pm 4$ keV, is a new transition. See Table 1 for the energies, intensities and assignments of the labeled proton groups.

A spectrum of beta-delayed alpha particles from $^{28}$P recorded concurrently with the proton spectrum is presented in Fig. 5. The energies, intensities and assignments of the labeled peaks, which all originate from $^{28}$P [25], are also listed in Table 1. While we observe the nine most intense alpha particle groups, the weakest, at 1667 keV, was not observed. This group was reported [25] to be $6.8 \pm 3.9$ % of the most intense alpha peak ($\alpha_6$) at 2106 keV. Thus our level of statistics and poorer alpha particle detector resolution (65 keV versus 20 keV reported by Ref.
could have prevented us from positively identifying this transition. An upper limit of 3% intensity (relative to the 100% group) was determined from the current experiment.

A partial decay scheme of $^{28}\text{P}$ is presented in Fig. 6. Total $\beta p$ and $\beta\alpha$ branches were measured in Ref. [25] by comparing the yield of each individual proton group, as well as the yield of each individual alpha group, to the yield of the 1.778 MeV $\gamma$-ray line which is associated with 95.5% of all $^{28}\text{P}$ beta decays [24]. This resulted in $\beta p$ and $\beta\alpha$ branches of $(13 \pm 4) \times 10^{-6}$ and $(8.6 \pm 2.5) \times 10^{-6}$, respectively [25]. The $1.5 \pm 0.6 \beta p/\beta\alpha$ ratio inferred from Ref. [25] compares favorably to the $1.4 \pm 0.4$ ratio of delayed protons to delayed alphas determined from the present results. Spins, parities and energies of the $^{28}\text{Si}$ levels were taken from Ref. [24]. The beta feeding to each state was determined based on the present yield of charged particles and the total $\beta p$ and $\beta\alpha$ branches determined by Ref. [25].

The delayed proton spectrum recorded during a 240 mC bombardment of 45 MeV protons on the same silicon targets as the 28 MeV bombardment is presented in Fig. 7. In addition to the $^{28}\text{P}$ peaks observed in the preceding bombardment, four additional proton groups, labeled $p_1$ through $p_4$, have been assigned to the beta-delayed proton emission of $^{27}\text{P}$, produced via the $^{28}\text{Si}(p,2n)^{27}\text{P}$ reaction. Protons groups $p_3$ and $p_4$, with energies of $731 \pm 2$ keV and $1324 \pm 4$ keV, were previously observed [13], while $p_2$, at $612 \pm 2$ keV, is a new transition. Our evidence for also assigning proton group $p_1$, with laboratory energy $466 \pm 3$ keV, to $^{27}\text{P}$ comes from comparing the yields of $^{28}\text{P}$ at 28 MeV and 45 MeV bombarding energies and observing a strong surplus of events at the higher bombarding energy from what would be expected if this peak were purely a result of the decay of $^{28}\text{P}$. The alpha particle spectrum at this bombarding energy was dominated by the alpha continuum from the decay of $^{8}\text{B}$ [26] (produced from carbon contaminants in the target), as well as alpha groups from the decays of $^{20}\text{Na}$ [27] and $^{24}\text{Al}$ [28]. No other alpha groups were discernible. (As discussed later, the observation of $^{24}\text{Al}$ $\beta\alpha$ also means a $\beta p$ contribution to the proton spectrum, which is in the form of a continuum between 300 and 1100 keV [7].) The results are summarized in Table 2.

Based upon energy considerations and barrier penetration calculations [13], these proton groups all result from the decay of $^{27}\text{Si}$ excited states to the $0^+$ isomeric state in $^{26}\text{Al}$ which lies 228 keV above the $5^+$ ground state. A partial decay scheme for $^{27}\text{P}$ is presented in Fig. 8. The $1/2^+$ ground state spin and parity of $^{27}\text{P}$ is taken from its mirror, $^{27}\text{Mg}$. Allowed beta decay of $^{27}\text{P}$ will populate either $1/2^+$ or $3/2^+$ excited states in $^{27}\text{Si}$, which can then de-excite through the emission of protons. Barrier penetration calculations indicate that the $\ell = 2$ proton transitions to the $0^+$ isomeric state are favored by over three orders of magnitude over possible $\ell = 4$ proton transitions to the $5^+$ ground state.

The estimated 0.07% $^{27}\text{P}$ beta-delayed proton branch was determined by relation to the known $\beta p$ branch of $^{28}\text{P}$, utilizing the relative yields of protons seen at the higher bombardment
energy and the calculated production cross sections. The latter were given by the statistical model fusion-evaporation code, ALICE [29]. Experience with using ALICE has revealed that this code will accurately predict the bombarding energy at which the cross section is at a maximum; however, once past the production peak, the predicted cross sections decrease much faster than has been observed. Thus, the production of $^{27}\text{P}$ was calculated at 45 MeV, while that of $^{28}\text{P}$ was determined first at 28 MeV (in each case, the predicted maximum of their respective excitation functions), then related to 45 MeV through the ratio of $^{28}\text{P}$ yields seen at the two bombardment energies.

The IAS (of the $^{27}\text{P}$ ground state) in $^{27}\text{Si}$ lies at 6.626 MeV excitation [24] which is bound to proton emission by 838 keV. The de-excitation of this state may only proceed through gamma-ray emission, and as the present experiment was limited to sampling only beta-delayed proton and alpha decay branches, the decay of the IAS was not observable. The 15% beta decay branch to this state was calculated assuming a log $f_t$ value of 3.30 and a 260 ms $^{27}\text{P}$ half-life.

B. Protons + Zinc Sulfide Bombardments

As with the protons on silicon experiments, a bombardment of 28 MeV protons on ZnS targets was performed. However, difficulties with the He-jet and the detectors made the results obtained unreliable. Nonetheless, we are able to interpret the $^{31}\text{Cl}$ beta-only proton decay results from the 45 MeV proton bombardments. Figure 9 shows a proton spectrum resulting from a 220 mC bombardment of 45 MeV protons on ZnS. The main $^{31}\text{Cl}$ and $^{32}\text{Cl}$ beta-delayed proton groups have been labeled. The proton assignments for $^{32}\text{Cl}$ were based on Ref. [25], while the $^{31}\text{Cl}$ assignments were from Ref. [13]. In addition to protons from $^{31}\text{Cl}$ and $^{32}\text{Cl}$, there is a significant amount of delayed protons from $^{25}\text{Si}$, produced from the aluminum backing disks through the $^{27}\text{Al}(p,3n)^{25}\text{Si}$ reaction. Nuclei made from the Al can escape the target and enter the He-jet through holes and cracks in the ZnS layer. Another possible source of background is from the known beta-delayed proton emitter, $^{24}\text{Al}$, which could be made from the aluminum backing disks through the $^{27}\text{Al}(p,p3n)^{24}\text{Al}$ reaction. However, the production threshold of this reaction is 42.9 MeV, which is just below the 45 MeV proton bombarding energy. While $^{24}\text{Al}$ could be made, the production cross section would be expected to be very small and with a 1.2 x 10^{-5} $\beta p$ branching ratio [7], any possible contribution from $^{24}\text{Al}$ to the proton spectrum of Fig. 9 can be ignored. Finally, in a separate bombardment of 45 MeV protons on zinc targets, no proton groups were observed.

Using the known intensities for $^{25}\text{Si}$ beta-delayed proton groups [23], and the observed intensity of the 905 keV proton group as a reference point, the amount of $^{25}\text{Si}$ contributing to each peak seen in Fig. 9 was determined. It was found that other than those from $^{25}\text{Si}$, there were no additional significant peaks (I_p ≥ 1%) above the 1524 keV proton group. Furthermore, the two weakest proton groups at 845 keV and 1173 keV reported in Ref. [13] could not be
positively identified in the present experiment separate from the large $^{25}\text{Si}$ beta-delayed proton background. Of the eight proton transitions reported in Ref. [13], only the 986 keV and 1524 keV proton groups could be confirmed as resulting from $^{31}\text{Cl} \beta p$ decay. The current results, as well as the results of Refs. [13, 14], are presented in Table 3.

The discrepancies between this measurement and the previous work [13] can be attributed to the presence of $^{25}\text{Si}$ in both data sets. Both experiments utilized the same ZnS targets. However, in the previous measurement, the targets were newer and probably had fewer cracks and holes in the ZnS; consequently the level of $^{25}\text{Si}$ contamination was much lower. It had been (correctly) assumed that any nuclides made from the Al backings would not have sufficient recoil energy to traverse the ZnS layer. Additionally, that experiment employed an 8.3 μm silicon ΔE, a 68 μm silicon E detector telescope, followed by a 200 μm E_reject detector. The reject counter served to eliminate protons above 2.7 MeV, as well as to eliminate positron associated events. The low-proton energy cutoff was slightly below 700 keV. Hence, they were unable to observe the full $^{25}\text{Si}$ beta-delayed proton spectrum. Thus, the proton groups in Table 3 in which the relative intensities are listed at ≤1% are, in order of increasing energy, most likely the 1727 keV, 1848 keV, 2082 keV and 2219 keV beta-delayed proton groups in $^{25}\text{Si}$, with the possibility that they result from the decay of $^{31}\text{Cl}$ excluded at the 99% confidence level. Likewise, the two proton groups at 845 keV and 1173 keV in Ref. [13] are also probably the 905 keV and 1221 keV $^{25}\text{Si}$ proton groups; however, a definitive determination was not possible. Additionally, the reported [13] relative intensities of the three highest energy proton groups are all consistent with the relative intensities of the $^{25}\text{Si} \beta p$ groups.

IV. DISCUSSION

From the experimental data for $^{27}\text{P}$, log $ft$ values between 4.7 and 6.1 were calculated, indicating allowed beta decays for transitions leading to proton emitting states in $^{27}\text{Si}$. From these values, the Gamow-Teller strength $B(\text{GT})$ of each transition was obtained through the relation; $B(\text{GT}) = 6170 \text{ sec/ft} \cdot B(\text{F})$, and by assuming no isospin mixing. A summation of $B(\text{GT})$ within 250 keV energy bins based on our experimental data is presented as a histogram in the bottom half of Fig. 10. Since no $\beta\gamma$ data were obtained, the observable experimental window is limited to a range from approximately 250 keV above the proton separation energy, $S_p$, to $2\text{mc}^2$ below the QEC.

The top half of Fig. 10 shows the results of shell model calculations of Ref. [13], using a $^{27}\text{P}$ predicted half-life of 215 ms. A full space d5/2-s1/2-d3/2 shell model was used to generate wavefunctions [17] for the $T = 3/2$ ground states of the $A = 27$ parents and all possible daughter states within the beta-decay energy window. The $1/2^+$ predicted $^{27}\text{P}$ ground state $J^\pi$ restricts allowed Gamow-Teller decay to states in $^{27}\text{Si}$ with spin-parities of $1/2^+$ and $3/2^+$. Values of the Gamow-Teller operator (<<στ>>) for each possible transition were determined from the calculated
wavefunctions. Multiplying $\langle \sigma \tau \rangle^2$ by the ratio of the GT and Fermi coupling strengths \((g_a/g_v)^2\) gives the Gamow-Teller strength of the transition. The value of \((g_a/g_v)^2\), as determined from the decay of the free neutron, is 1.51. The calculated B(GT) values shown have been multiplied by a 0.60 quenching factor [20], which has been observed in comparisons between theoretical calculations and medium energy (p,n) experiments. Most of the GT strength is found between 7 and 10 MeV excitation in the beta daughter.

A comparison between the top and bottom halves of Fig. 10 reveals that the majority of the theoretical GT strength is concentrated below the experimental detection limits. Approximately 25\% of the total predicted strength was expected to fall within our detection energy window, and in referring to Fig. 10, approximately 32\% of this summed strength that was predicted to fall between 7.75 and 10.5 MeV was identified. Although the current results improve upon the agreement between the shell-model calculation and the experimental results obtained in the earlier work of Äystö et al. [13], there still remains a substantial discrepancy. Inspection of Fig. 7 indicates the presence of a continuum of protons underneath the most intense proton peaks. The amount of $^{24}$Al present in this spectrum can be inferred from the intensity of its 1.587 MeV alpha group and the measured $\beta_p/\beta_\alpha$ branching ratio of \((4.7 \pm 0.2) \times 10^{-2}\) [7]. An analysis of the delayed alpha spectrum recorded at 45 MeV indicates that \(~10\%\) of the continuum under the proton peaks (which is centered at \(~750\) keV) in Fig. 7 is due to the decay of $^{24}$Al. While delayed protons from $^{24}$Al represent a component, it is clear that they are not the only contributor to this proton "background". Thus it is possible that this continuum of protons could account for some of the missing strength between 8 and 9 MeV excitation. Additionally, the presence of weak, unresolved $^{27}$P $\beta_p$ groups in Fig. 7 which could contribute significantly to this "missing" GT strength cannot be excluded.

As the $^{27}$Si excitation energy increases, exceedingly small proton branches are required to produce B(GT) values of the order predicted. In Fig. 10, consider the predicted strengths at $E^*(^{27}$Si) = 9.9 and 10.4 MeV. Such states, if populated, could decay through the emission of protons with lab energies of \(~2.1\) and \(~2.6\) MeV, respectively, to the $0^+$ isomeric state in $^{26}$Al. Based on the level of statistics in Fig. 7, there would only need to be \(~19\) events and \(<1\) event at these two proton energies to produce a GT strength of 0.1 for each (respective) state. Such small proton branches are below the sensitivity of the current experiment.

As mentioned in the introductory paragraphs, a similar shell model calculation was used to determine Gamow-Teller strengths for $^{31}$Cl decay. However, the presence of significant amounts of beta-delayed protons from $^{25}$Si in the final proton spectrum precluded the possibility of making a sensitive analysis of the data set for the direct comparison of GT strengths.
V. SUMMARY

In a series of proton bombardments on natSi and ZnS targets, the beta-delayed proton decays of the $T_z = -3/2, A = 4n + 3$ series nuclides $^{27}$P and $^{31}$Cl have been investigated using the He-jet recoil transport technique and low energy charged-particle detector telescopes. Beams of 28 MeV and 45 MeV protons bombarding silicon targets were used to study the decays of $^{28}$P and $^{27}$P, respectively. A new beta-delayed proton group in $^{28}$P with a lab energy and a relative intensity (to the 100% group at 679 keV) of $1452 \pm 4$ keV and $2 \pm 1\%$ was observed. In $^{27}$P, two new beta-delayed proton groups with lab energies of $466 \pm 3$ keV and $612 \pm 2$ keV and relative intensities (to the 100% group at 731 keV) of $9 \pm 2\%$ and $97 \pm 3\%$, respectively, were observed. A 45 MeV proton beam, bombarding ZnS targets, was used to examine the beta-delayed proton decay of $^{31}$Cl. It was revealed that the unexpected presence of $^{25}$Si, made from the aluminum target backings, in the data of Ref. [13] had resulted in the misassignment of several transitions to the decay of $^{31}$Cl.

The Gamow-Teller component of the preceding beta decay of each proton transition observed from the emitter state, $^{27}$Si (for $^{27}$P decay), was compared to predictions obtained from shell model calculations. While a portion of the predicted strength was positively identified, it was not possible to discern the complete beta decay strength because certain states were very weakly populated. The decays of these states could involve the emission of protons with intensities that are below the current level of statistics.

It would be very instructive to study the complete phase space of the decays of $^{27}$P and $^{31}$Cl thereby testing the shell model calculations to their full extent. Such an endeavor would require mass separation to examine both the beta-delayed gamma-ray and proton spectra free of most contaminating nuclides.

a) Refer to Fig. 4. for protons (p1...p7) and to Fig. 5. for alphas (α1...α10).
b) Energies are reported in keV in the lab. system with proton groups p1 through p6 and alpha particle groups α1 through α10 calculated from the assignments made in Refs. [24, 25] with proton group p7 measured in this work.
c) Based on 11586 keV proton separation energy to the ground state of $^{27}$Al and on 9986 keV alpha particle separation energy to the ground state of $^{24}$Mg.
d) These peaks were used, in part, to define the proton calibration.
e) Defined.
Table 2. $^{27}$P beta-delayed proton groups.

a) Energies are reported in keV in the laboratory system.

b) These proton groups could not be positively identified because of the significant levels of contamination of $^{25}$Si beta-delayed protons (see text).

c) Defined.

Figure Captions

Fig. 1. Schematic diagram of the multiple target/multiple capillary He-jet setup and the detector arrangement used in these experiments.

Fig. 2. Cross sectional schematic view of one low-energy charged-particle gas $\Delta E$-gas $\Delta E$-silicon E detector telescope.

Fig. 3. Proton spectrum from a 3 mC bombardment of 40 MeV $^3$He + natMg recorded during the calibration phase of the $^{31}$Cl experiment. All peaks are due to the $^p\beta$ decay of $^{25}$Si. Associated with a proton group is a peak from summing with beta particles from its preceding beta decay. The intensity of each sum peak is $\sim 3.5\%$ of its associated proton group and the difference in energy between the two peaks represents the average energy loss of the beta particle in the silicon detector.

Fig. 4. Proton spectrum recorded during a 290 mC bombardment of 28 MeV protons on natSi targets. Peaks labeled $p_1 ... p_7$ are noted, while those marked by $p'$ are peaks from summing with beta particles. See text.

Fig. 5. Alpha spectrum recorded simultaneously with Fig. 4. See text.

Fig. 6. $^{28}$P partial decay scheme. The solid lines indicate those transitions observed during the present experiment.

Fig. 7. Proton spectrum recorded during a 240 mC bombardment of 45 MeV protons on natSi targets. See text.

Fig. 8. Proposed $^{27}$P partial decay scheme. Those transitions observed in the present experiment are shown as a solid line.

Fig. 9. Proton spectrum recorded during a 220 mC bombardment of 45 MeV protons on ZnS. The main proton groups from $^{31}$Cl and $^{32}$Cl are indicated. The peaks marked with an asterisk are the main $^{25}$Si beta-delayed proton groups produced on the aluminum backings of the targets. See text.

Fig. 10. Gamow-Teller strength function for $^{27}$P beta decay showing (a) theoretical distribution from shell model calculations and (b) from experiment. $S_p$, $I_{AS}$ and $Q_{EC}$ denote the locations, relative to the $^{27}$Si ground state, of the proton separation energy, the $T = 3/2$ isobaric analog state and the $^{27}$P ground state.
