Abstract
Background: The neuropeptide RFamide-related peptide-3 (RFRP-3; mammalian ortholog to gonadotropin-inhibiting hormone) can inhibit luteinizing hormone (LH) release and increases feeding, but the regulation and development of RFRP-3 neurons remains poorly characterized, especially in mice. Methods and Results: We first confirmed that peripheral injections of murine RFRP-3 peptide could markedly suppress LH secretion in adult mice, as in other species. Second, given RFRP-3’s reported orexigenic properties, we performed double-label in situ hybridization for metabolic genes in Rfrp neurons of mice. While Rfrp neurons did not readily coexpress neuropeptide Y, thyrotropin-releasing hormone, or MC4R, a small subset of Rfrp neurons did express the leptin receptor in both sexes. Surprisingly, we identified no changes in Rfrp expression or neuronal activation in adult mice after acute fasting. However, we determined that Rfrp mRNA levels in the dorsal-medial nucleus were significantly reduced in adult obese (Ob) mice of both sexes. Given the lower Rfrp levels observed in adult Ob mice, we asked whether leptin might also regulate RFRP-3 neuron development. Rfrp gene expression changed markedly over juvenile development, correlating with the timing of the juvenile ‘leptin surge’ known to govern hypothalamic feeding circuit development. However, the dramatic developmental changes in juvenile Rfrp expression did not appear to be leptin driven, as the pattern and timing of Rfrp neuron development were unaltered in Ob juveniles. Conclusion: Leptin status modulates RFRP-3 expression in adulthood, but is not required for normal development of the RFRP-3 system. Leptin’s regulation of adult RFRP-3 neurons likely occurs primarily via indirect signaling, and may be secondary to obesity, as only a small subset of RFRP-3 neurons express the long form of the leptin receptor (LepRb).

Introduction

Neuronal networks of the hypothalamus integrate peripheral endocrine and metabolic signals to regulate gonadotropin-releasing hormone (GnRH) neurons, which in turn stimulate the reproductive axis. In most cases, hormonal and metabolic information are transmitted to GnRH neurons indirectly via upstream reproductive neural circuitry. One possible intermediary neuropeptide is RFamide-related peptide 3 (RFRP-3), the mammalian ortholog of avian gonadotropin-inhibiting hormone [1, 2]. In rodents, RFRP-3 treatment inhibits both GnRH neuronal activity and luteinizing hormone (LH) secretion through central GnRH-dependent mechanisms [3–6]. In mice and rats, some GnRH neurons are apposed by
Leptin, a hormone secreted from adipocytes, has strong effects on hypothalamic regulation of satiety, energy expenditure, and body weight, not to mention a stimulatory (permissive) role in reproductive function. Obese mice (Ob) have a nonfunctional leptin gene and are overweight, hyperphagic, have low LH levels, and are infertile [16, 17], illustrating the importance of leptin in maintenance of both energy homeostasis and reproduction. Leptin does not directly regulate GnRH neurons, as the long form of the leptin receptor (LepRb), which is responsible for signal transduction, is not expressed in GnRH neurons [18, 19]. Rather, leptin acts on GnRH neurons indirectly, through upstream intermediates which have yet to be fully identified. RFRP-3 neurons may be one potential relay system through which leptin signals are mediated, as the DMN (where RFRP-3 neurons reside) is a leptin-responsive brain region [20–22]. Central injections of RFRP-3 not only inhibit LH secretion, but also stimulate feeding behavior [23, 24]. Moreover, RFRP-3 neurons are activated by chronic mild food restriction in hamsters [25], and RFRP-3’s receptor, Gpr147, is required in mice to suppress LH secretion after acute food deprivation (FD) [26], suggesting that RFRP-3 plays a role in both energy balance and reproduction, as does leptin [27]. Thus, leptin might inhibit the production and/or secretion of RFRP-3 in order to facilitate reproductive function and/or suppress feeding behavior.

In addition to its roles in adulthood, leptin has important developmental effects on the hypothalamus. During the second week of postnatal life, serum leptin levels increase drastically and transiently in a postnatal leptin ‘surge’ [28]. This temporary increase in juvenile leptin levels regulates the development of axonal projections from the arcuate nucleus to the DMN, as well as other brain regions [29, 30]. We previously demonstrated that DMN Rfrp expression, as measured by cell number and Rfrp mRNA levels per cell, is dramatically higher in juveniles on postnatal day (PND) 10 than at birth [9], but whether this developmental difference is caused, fully or in part, by the juvenile leptin surge is unknown.

In this study, we addressed whether neural Rfrp expression is regulated by metabolic manipulations, such as leptin deficiency seen in Ob animals or short-term FD. We also ascertained whether the developmental maturation of the neural Rfrp system is leptin dependent, owing to the developmental surge in leptin secretion during the juvenile period. Specifically, we determined whether (1) the mouse RFRP-3 peptide suppresses LH secretion, as reported for the rat RFRP-3 peptide variant in other species, (2) Rfrp neurons coexpress important metabolic genes, including Leprb, that are known to be expressed in the DMN, (3) Rfrp expression and/or neuronal activation is enhanced during FD or altered in adult Ob mice, and (4) the developmental pattern of Rfrp expression in postnatal mice parallels developmental leptin secretion (the juvenile leptin surge), and if so, whether normal Rfrp development is dependent on leptin signaling.

Materials and Methods

Animals, Gonadectomies, and Tissue Collection

Experiments utilized either C57BL6 mice or mice from the Ob strain [wild-type (WT) and Ob]. Mice from the Ob line were purchased from Harlan Laboratories and maintained on a C57BL6 background in the lab. All animals were housed on a 12:12-hour light-dark cycle, with food and water available ad libitum (ad lib), except where indicated in experiment 3. All experiments were conducted in accordance with the NIH Animal Care and Use Guidelines and with approval of the Animal Care and Use Committee of the University of California, San Diego, Calif., USA.

For adult C57BL6 mice, 7- to 9-week-old female (diestrous) or male mice were anesthetized with isoflurane, weighed, blood was collected via retro-orbital bleeding, and then they were rapidly decapitated. Prior to RFRP-3 injections and for the FD experiment, all C57BL6 mice were bilaterally gonadectomized (GDX), as previously described [9]. Gonadectomy was implemented to promote high levels of circulating LH for RFRP-3 or food restriction to inhibit, and to simultaneously control for differences in sex steroids between individuals since estradiol and testosterone can both mildly suppress Rfrp levels in mice of both sexes [9, 31]. For adult Ob mice, 7- to 8-week-old female or male WT or Ob mice were GDX (again, to control for sex steroids between genotypes and allow for maximal Rfrp expression levels in the absence of steroid inhibition) and then sacrificed 7 days later for blood and tissue collection.

For developmental experiments, infantile and juvenile pups were generated by C57BL6 breeder pairs or heterozygous Ob mice.
breeder pairs (producing WT, Ob and heterozygous littermates). The date of birth was designated as PND 1. Newborn and juvenile pups of various ages were anesthetized with isoflurane, weighed, and rapidly decapitated. Trunk blood was collected from each animal to measure serum leptin levels. For mice of the Ob strain, tail samples were taken postmortem to determine the Ob genotype. Note that the obesity phenotype in Ob mice is not present until 4 weeks of age or later [16, 17].

Brains from all animals were collected at sacrifice, frozen on dry ice, stored at −80°C, and then sectioned on a cryostat into five coronal series of 20-μm brain sections which were thaw-mounted onto Superfrost-plus slides. Slides were stored at −80°C until use for in situ hybridization (ISH).

**Hormone Assays**

Blood from adult animals was collected by retro-orbital bleed. Blood from juvenile animals was collected via trunk blood. Serum LH was measured by the UVA Ligand Core (range: 0.04–3.4 ng/ml). Serum leptin was measured using the Quantikine Mouse Leptin ELISA Kit (R&D Systems) following the manufacturer’s protocol (range: 1.25–80 ng/ml).

**Regulation and Development of RFRP-3 Neurons in Mice**

**Experiment 1: Does RFRP-3 Inhibit LH Secretion in Mice?**

The conserved role of RFRP-3 in the inhibition of LH secretion is assumed to be true in mice, but, surprisingly, data demonstrating this has not yet been reported. In order to test if the mouse RFRP-3 peptide is functionally able to suppress LH secretion in mice, as occurs with other RFRP-3 variants in other species, adult ovariectomized mice were subjected to either 100 ng or 500 ng of the murine RFRP-3 peptide (VMNEAGTRSHFPSPQRF-NH2, Genscript USA Inc.) dissolved in 100 μl of saline or saline vehicle.
Twenty minutes after intraperitoneal injection, blood was collected by retro-orbital bleed and the serum was assayed for LH (n = 7–8 per treatment group).

**Experiment 2: What Metabolic Neuropeptides and Receptors Are Expressed in Rfrp Neurons?**

The phenotypic identity of Rfrp neurons is virtually unknown. Besides estrogen and glucocorticoid receptors, other receptors or secreted cofactors, such as neurotransmitters or neuropeptides, have not been identified in Rfrp neurons. Any number of metabolic genes expressed in the DMN region may colocalize with Rfrp, and if so, would give insight to the regulation and potential metabolic functions of RFRP-3 neurons. We therefore examined whether transcripts of important metabolic genes already known to be expressed in the DMN specifically colocalize with Rfrp. Adult C57BL6 mice of both sexes (females in diestrus) were sacrificed and their brains collected for double-label ISH analyses. Using alternate series of coronal brain sections (encompassing the entire rostral to caudal span of the DMN) from each mouse, we examined in 4 separate assays the coexpression of neuropeptide Y (Npy) [43–45], Thr [34, 46], LepRb [47], and melanocortin receptor 4 (Mcr4) [48] in Rfrp neurons (n = 4–6 per sex).

**Experiment 3: Is Rfrp Expression or Neuron Activity Responsive to Short-Term Metabolic Challenge?**

Given that RFRP-3 treatment increases food intake [7, 49] and that a subset of Rfrp neurons express the leptin receptor (experiment 2), it is possible that transiently diminished serum leptin levels achieved via short-term FD may alter Rfrp expression and/or Rfrp neuronal activation. Furthermore, a recent report demonstrated that LH secretion is not suppressed after 12 h of FD in Gpr147 knockout mice, suggesting RFRP-3 is essential during prolonged fasting. To determine if peripherally administered murine RFRP-3 peptide can suppress LH secretion in mice, as occurs with other RFRP-3 variants in other species, 100 ng of murine RFRP-3 peptide was injected i.p. in adult GDX female mice. Both the 100-ng and 500-ng doses of murine RFRP-3 were able to significantly suppress LH secretion, by nearly 70% (fig. 1; p < 0.05). There was no difference in the efficacy of the two doses of murine RFRP-3 on LH suppression.

**Experiment 4: Is Rfrp Expression Altered in Adult Ob Animals?**

Since experiment 2 found that a subset of Rfrp neurons express LepRb, we hypothesized that Rfrp expression may be leptin regulated. To determine if Rfrp levels are altered with chronic leptin deprivation, we measured Rfrp neuron numbers and cellular Rfrp expression levels using single-label ISH in adult male and female GDX Ob mice (leptin deficient) and their WT GDX littermates (n = 5–7 animals per genotype per sex).

**Experiment 5: Does Rfrp Expression during Postnatal Development Coincide with Serum Leptin Levels?**

Experiment 4 demonstrated that adult Ob mice display altered Rfrp expression, suggesting that leptin may regulate RFRP-3 neurons. In development, there is a large transient rise in serum leptin that occurs during the second week of life in mice. Around this same age, Rfrp expression is significantly higher than on the day of birth [9]. In order to see if the juvenile leptin surge coincides with developmental changes in Rfrp neurons, C57BL6 pups were sacrificed by rapid decapitation on PND 1, 3, 6, 8, 10, 12, 14, and 16 (n = 5–9 animals per age, per sex). Only litters of 4–8 pups were used. Trunk blood was collected for serum hormone analysis, and brains were collected and frozen on dry ice. For each sex, brain slices containing the entire DMN were assayed and analyzed for Rfrp expression by single-label ISH, using the HE and LE Rfrp cell criteria described previously (see the section ‘Single-label and Double-Label ISH’ above) [36]; each sex was assayed independently. Serum leptin was measured by ELISA. Along with the postnatal mice, cohorts of control adult diestrous female or male mice were simultaneously assayed for Rfrp expression and serum leptin levels.

In a complementary experiment, to determine if the long-term leptin receptor is expressed in juvenile Rfrp neurons at different developmental stages, an alternate set of brain slides from female PND 1, 10, and 12 mice (along with adult diestrous female controls) was checked for LepRb coexpression in Rfrp neurons using double-label ISH (n = 6–7 animals per age group).

**Experiment 6: Are the Juvenile Changes in Rfrp Expression during Development Dependent on Leptin?**

Given the synchronous developmental changes in juvenile Rfrp expression and postnatal leptin secretion observed in experiment 5, we hypothesized that the developmental changes in Rfrp neurons may be leptin dependent. To test this, we repeated experiment 5 using heterozygous Ob breeding pairs to produce WT, Ob, and heterozygous pups. Brains, trunk blood, and tail snips for genotyping were collected on PND 1, 6, 10, 12, and 16. Only litters of 4–8 pups were used. Brains from WT and Ob males of these various postnatal ages were analyzed for Rfrp mRNA expression levels via single-label ISH (n = 5–9 animals per age per genotype). Serum leptin for each animal was measured via ELISA to confirm the presence or absence of circulating leptin.

**Results**

**Experiment 1: The Murine RFRP-3 Peptide Inhibits LH Secretion in Adult Female Mice**

To determine if peripherally administered murine RFRP-3 peptide can suppress LH secretion in mice, as occurs with other RFRP-3 variants in other species, 100 ng or 500 ng of RFRP-3 or saline was injected i.p. in adult GDX female mice. Both the 100-ng and 500-ng doses of murine RFRP-3 were able to significantly suppress LH secretion, by nearly 70% (fig. 1; p < 0.05). There was no difference in the efficacy of the two doses of murine RFRP-3 on LH suppression.
Experiment 2: A Subset of Rfrp Neurons Express LepRb mRNA

Double-label ISH was performed for energy balance-related genes known to be expressed in the DMN [34, 43–48] to determine if they are coexpressed in Rfrp neurons of adult male or female mice. We found that virtually no Rfrp neurons coexpressed Npy or Trh, despite notable Npy and Trh expression in the same DMN region, often near Rfrp neurons (fig. 2; table 1). Next, to assess the possibility that metabolic hormones/neuropeptides...

Adult diestrous (DE) females and intact male mice were assayed for neuropeptide Y (NPY), TRH, LepRb, or Mc4r mRNA in Rfrp cells in the DMN. Values are average percent coexpression ± SEM. n = 4–6 animals per sex.

might directly regulate the RFRP-3 system, we looked for coexpression of several metabolic signaling factor receptors in Rfrp neurons. LepRb mRNA was found to be notably coexpressed in a subset of Rfrp neurons, suggesting that a proportion of adult Rfrp neurons may be leptin responsive. The degree of LepRb-Rfrp coexpression was similar in both sexes (∼15%). An even smaller subset of Rfrp neurons (∼8%) in both sexes was found to coexpress the primary melanocortin receptor, Mc4r. A summary of the coexpression levels for each gene with Rfrp is in table 1.

Experiment 3: Rfrp Neurons in Mice Appear Unresponsive to 12-Hour FD

To test if energetic challenge induced by short-term FD modifies Rfrp mRNA expression levels or the activity of RFRP-3 neurons, adult female mice were subjected to short-term (12-hour) FD. Demonstrating the effectiveness of the energetic challenge, 12-hour FD mice had a significant decrease in body weight (5.3%; p < 0.05) and significant decreases in serum LH and leptin relative to ad lib control females (fig. 3a–c; p < 0.05). However, despite this negative impact of 12-hour FD on body weight and endocrine physiology, there were no significant differences in the total number of detectable Rfrp neurons compared to ad lib and FD animals of both sexes (data not shown). In the brain, the total number of detectable Rfrp neurons was not significantly different between Ob and WT mice in either sex (fig. 4a, b). However, using the HE and LE Rfrp cell criteria, there was a significant decrease in the number of HE Rfrp neurons in female Ob mice compared to female WTs (fig. 4a; p < 0.05), with no significant differences in the number of LE Rfrp cells between genotypes. Likewise, a similar reduction in the number of HE Rfrp neurons was detected in male Ob mice compared to WT male littermates (fig. 4b; p < 0.05). In addition to these changes in cell number, the total level of Rfrp mRNA in the DMN was significantly lower in both male and female Ob mice compared to their WT littermate controls (fig. 4a, b; p < 0.05).

Experiment 4: Rfrp Expression Is Decreased in Adult Ob Mice of Both Sexes

This experiment assessed whether there are notable differences in Rfrp expression in adult Ob (leptin deficient) and WT mice that were all GDX beforehand to remove any masking effects of circulating E2 (which moderately decreases Rfrp expression). As expected, Ob animals of both sexes were significantly heavier, weighing almost twice as much than their WT counterparts (p < 0.05, data not shown). In the brain, the total number of detectable Rfrp neurons was not significantly different between Ob and WT mice in either sex (fig. 1a, b). However, using the HE and LE Rfrp cell criteria, there was a significant decrease in the number of HE Rfrp neurons in female Ob mice compared to female WTs (fig. 4a; p < 0.05), with no significant differences in the number of LE Rfrp cells between genotypes. Likewise, a similar reduction in the number of HE Rfrp neurons was detected in male Ob mice compared to WT male littermates (fig. 4b; p < 0.05). In addition to these changes in cell number, the total level of Rfrp mRNA in the DMN was significantly lower in both male and female Ob mice compared to their WT littermate controls (fig. 4a, b; p < 0.05).

Experiment 5: Changes in Rfrp Expression over Postnatal Development Correlate with the Leptin Surge

We previously reported that Rfrp levels in the brain are dramatically higher in juvenile mice (on PND 10) compared to birth. Since experiment 4 demonstrated that Rfrp expression is significantly altered in adult Ob animals of both sexes, we hypothesized that the juvenile leptin surge [28] might govern the developmental changes in Rfrp expression. We first determined whether there was a correlation between juvenile leptin levels and postnatal developmental changes in Rfrp expression. C57BL6 mice of both sexes were sacrificed on PND 1, 3, 6, 8, 10, 12, 14, and 16, and their brains were assayed for Rfrp expression (fig. 5) and compared to serum leptin levels at each age. The total number of detectable Rfrp neurons was highest at birth and was significantly lower at later postnatal ages, with the lowest number of Rfrp neurons in adulthood (diestrous stage for females; fig. 6a). However, the amount of Rfrp expressed per cell was lowest at birth and increased substantially with age. Indeed, the
Fig. 3. Effects of short-term food deprivation on Rfrp expression and Rfrp neuron activation in GDX female mice. A 12-hour FD had a significant effect on the change in body weight (p < 0.05) with deprived animals losing almost 6% of body weight on average. B Serum LH is significantly less in 12-hour FD GDX animals than ad lib animals (p < 0.05). C Serum leptin is significantly less in 12-hour FD GDX animals than ad lib animals (p < 0.05). D Representative photomicrographs of single-label ISH for Rfrp mRNA in ad lib and 12-hour FD female GDX mice. 3V = Third ventricle. E The total number of Rfrp neurons is not significantly different between ad lib and 12-hour FD animals. F The total number of Rfrp mRNA is not significantly different between ad lib and 12-hour FD animals. G Representative photomicrographs of double-label ISH for c-fos and Rfrp mRNAs in ad lib and 12-hour FD female GDX mice. Double-labeled c-fos and Rfrp (green arrowhead), single-labeled c-fos cells (yellow arrow), and single-labeled Rfrp neurons (blue arrow) are shown. H Quantification of percent c-fos and Rfrp coexpression in ad lib and 12-hour FD animals showed no significant difference between the two groups.
**Fig. 4.** *Rfrp* expression in adult Ob male and female GDX mice.

a  Representative photomicrographs of single-label ISH for *Rfrp* mRNA in WT and Ob female GDX mice. 3V = Third ventricle.

b  Quantification of total *Rfrp* neurons, HE *Rfrp* neurons, LE *Rfrp* neurons, and total *Rfrp* mRNA from single-label ISH in female GDX mice. The number of HE cells and the total *Rfrp* mRNA was significantly less in Ob females than WT littermates (p < 0.05).

There were no significant differences between the total number of *Rfrp* neurons or number of LE cells.

c  Quantification of total *Rfrp* neurons, HE *Rfrp* neurons, LE *Rfrp* neurons, and total *Rfrp* mRNA from single-label ISH in male GDX mice. The number of HE cells and the total *Rfrp* mRNA was significantly less in Ob males than WT littermates (p < 0.05). There were no significant differences between the total number of *Rfrp* neurons or number of LE cells.
total amount of $Rfrp$ mRNA in the DMN increased with postnatal development, beginning to rise around PND 6 and peaking at PND 12 before dropping again at subsequent older ages (fig. 6b; p < 0.05). This robust increase in total $Rfrp$ mRNA during the 2nd week of postnatal life appears to reflect a large increase in the number of HE $Rfrp$ cells, which are virtually absent at birth, but substantially increase in abundance around PND 6 and peak at maximal levels at PND 12 before dropping slightly at subsequent older ages (fig. 6c; p < 0.05). Unlike HE $Rfrp$ cells, the number of LE cells decreases slowly and steadily throughout these postnatal ages, with the lowest number of LE cells in adulthood (fig. 6d; p < 0.05). Virtually identical results were found in similarly aged male mice (data not shown).

Serum leptin levels were measured in each animal to see if they correlated with $Rfrp$ levels. For both sexes, mean serum leptin levels were essentially undetectable at birth (PND 1) and on PND 3, and were first readily detectable at PND 6. Leptin levels increased robustly during the second week of life, peaking at PND 10 and 12 (the leptin surge), and subsequently began to fall on PND 14 and 16, being low again in adult animals (fig. 6e; p < 0.05). Leptin levels were significantly higher than adult female (diestrous) levels at all postnatal ages examined, except for PND 1 and 3 (p < 0.05). Interestingly, these postnatal changes in leptin levels correlated well with the observed increases in the number of HE $Rfrp$ cells and total $Rfrp$ mRNA, with each starting to increase around PND 6 and reaching maximal levels around PND 10 and 12 (fig. 6).

**Experiment 6: Juvenile $Rfrp$ Expression Is Not Dependent on Leptin during Development**

The dramatic developmental increase in HE $Rfrp$ neurons and total $Rfrp$ mRNA observed around PND 10 and 12 correlates with the zenith of the juvenile leptin surge (experiment 5), suggesting that the two events may be related. To test this possibility, we determined whether $Rfrp$ neurons coexpress LepRb during specific postnatal ages.
and whether the normal developmental pattern and levels of Rfrp expression are altered in juvenile mice lacking leptin. In postnatal brains examined for Rfrp/LepRb coexpression, a subset of Rfrp cells clearly coexpressed notable LepRb mRNA (fig. 7a); the degree of coexpression did not vary with age, being 15–20% from birth through adulthood (fig. 7b).

To determine if leptin signaling is required, directly or indirectly, for the normal pattern of Rfrp neuron development in juveniles, female Ob and WT brains were analyzed for Rfrp expression on PND 1, 6, 10, 12, and 16 (fig. 8, 9). Despite the strong correlation between developmental Rfrp and leptin changes observed in normal mice, there were no significant differences in the number of Rfrp neurons during the first 2 weeks of life. of Rfrp neurons, total amount of Rfrp mRNA, or the number of HE and LE Rfrp cells between Ob and WT mice at any developmental age (fig. 9a–d). The same developmental pattern in Rfrp expression seen in experiment 5 was observed in both genotypes, with identical magnitude increases detected in total Rfrp mRNA and the number of HE cells. Moreover, all Rfrp expression increases occurred at the same specific postnatal ages, regardless of genotype. Confirming the genotypes and leptin milieu, serum leptin was significantly elevated between PND 6 and 12 (representing the leptin surge), and lower on PND 16 than 12 in WT animals (p < 0.05), but remained undetectable in Ob animals at all ages (fig. 9e).

**Discussion**

The physiological roles RFRP-3 plays and how the hypothalamic RFRP-3 system develops and is regulated are still poorly understood. In addition to providing the first demonstration of the ability of peripherally administered RFRP-3 to potently inhibit LH secretion in vivo in mice, our current findings also show that a subset of RFRP-3 neurons express the long form of the leptin receptor and that Rfrp mRNA expression is diminished in Ob (leptin-deficient) animals of both sexes. We also demonstrate that Rfrp expression changes in a dramatic manner in postnatal development, mirroring age-specific juvenile changes in serum leptin. However, examination of the developmental maturation of Rfrp neurons in Ob pups revealed that neither the timing nor magnitude of these developmental changes in Rfrp expression are dependent on leptin.

Despite the reported effect of the rat variant of RFRP-3 to inhibit LH secretion in many species, including rodents (rats and hamsters), the effect of the murine variant of RFRP-3 on LH has not been reported in any species, including mice themselves. As the RFRP-3 field moves towards transgenic and knockout animals [26, 50], mouse models will become increasingly important and under-
standing murine RFRP-3 pharmacology and physiology is essential. Our present finding of markedly suppressed LH secretion 20 min after peripheral injection of two doses of murine RFRP-3 in adult female mice matches the results found in rats, hamsters, and sheep using the rat RFRP-3 peptide [2, 51–54]. Until just recently, RFPR-3 of any variant had surprisingly never been administered to mice. León et al. [26] reported that a truncated rat RFRP-3 peptide given via intracerebroventricular injection modestly decreased serum LH (by ∼25%) in WT GDX female mice. That reduction in LH was considerably less than the suppressive effects of peripheral murine RFRP-3 observed in the present study, in which we found ∼70% decrease in serum LH after peripheral murine RFRP-3 injections at two different doses. Besides potential species differences in murine versus rat RFRP-3 peptide efficacy, the difference in magnitude of effect might be due to dosing or the route of administration. Interestingly, the 100- and 500-ng doses were equally effective in suppressing LH secretion, suggesting that the suppressive effect of RFRP-3 may already be maximal near the 100-ng dose. As our RFRP-3 was administered peripherally, we cannot discern at what level(s) of the HPG axis the lowered LH secretion is attributable to. However, most data in rodents suggests that RFRP-3’s effects on LH are induced in the brain, via diminished GnRH signaling, rather than at the pituitary [8]. Yet, one study recently described in vitro effects of RFRP-3 on the pituitary in murine gonadotrope LβT2 cells [55].

Several studies have demonstrated an orexigenic effect of RFRP-3 [7, 24, 49], suggesting that RFRP-3 may be involved in receiving and/or transmitting energy balance signals. Both neuropeptide Y and thyrotropin-releasing hormone (TRH) are neuropeptide cell populations that reside in the DMN, and are even expressed in a similar pattern as Rfrp [34, 45]. However, Rfrp did not colocalize with either of these neuropeptides, demonstrating that it is a unique neuropeptide population with. We also examined two metabolic hormone receptors, the long-form leptin receptor, LepRb, and a melanocortin receptor,
Mc4r, which are also expressed in the DMN. A small subset of Rfrp neurons expressed each of these receptors, with the leptin receptor being the more prominently expressed, suggesting that some Rfrp neurons may be a direct target of leptin signaling. However, most Rfrp neurons did not express LepR, suggesting that any major effects of leptin signaling – or its absence – on Rfrp neurons may in fact be indirect.

Ob mice are infertile due to a lack of gonadotropin secretion [27], and since RFRP-3 is known to inhibit LH secretion, and some Rfrp neurons express the leptin receptor, we hypothesized that Rfrp expression would be higher in

Fig. 9. Summary of changes in Rfrp expression on PND 1, 6, 10, 12, and 16 in female Ob and WT animals. a Quantification of total number of Rfrp neurons during the leptin surge. There were no significant changes between genotypes. b Quantification of total Rfrp mRNA during the leptin surge. Rfrp expression is significantly higher on PND 10, 12, and 16 than on PND 1 or 6 (p < 0.05). c Quantification of the number of HE Rfrp neurons during the leptin surge. The number of Rfrp neurons is significantly higher on PND 10, 12, and 16 than on PND 1 or 6 (p < 0.05). d Quantification of the number of LE Rfrp neurons during the leptin surge. Different letters indicate significantly different groups (p < 0.05). e Serum leptin concentration in Ob and WT female mice as measured by ELISA. Leptin is highest on PND 10 and 12, dropping on 16, demonstrating the postnatal leptin surge. Leptin concentration in WT mice were significantly elevated between PND 6 and 16, peaking around PND 12 (p < 0.05). Leptin was not detectable on the day of birth in WT mice or in Ob animals at any age.
Ob mice. However, using GDX adult Ob males and females, we found the opposite outcome: Rfrp expression is lower in adult Ob mice than their WT littermates. This was true for both sexes. During the writing of this manuscript, Rizwan et al. [56] published data suggesting that RFRP-3 neurons are not regulated by leptin. That study’s immunohistochemical data showed no difference between the number of RFRP-3-immunoreactive neurons in GDX, E2-replaced Ob mice and WT littermates, and minimal phosphorylation of signal transducer and activator of transcription 3 in RFRP-3 neurons after leptin injections. Those results suggest that RFRP-3 neurons are not directly regulated by leptin and that RFRP-3-immunoreactive levels are unaffected by leptin deficiency, differing from our present results in which Rfrp levels were significantly diminished in Ob mice. It is possible that the exogenous E2 replacement in the Rizwan study may have masked differences between WT and Ob animals, as E2 moderately represses Rfrp [9, 31], and may have done so similarly in both genotypes. Our present data quantifying gene expression (rather than protein) levels demonstrates that total Rfrp mRNA levels are significantly repressed in GDX Ob animals (no E2 given, so Rfrp expression is not being inhibited by sex steroids). Additionally, in our Ob mice, we identified a primary deficit in Rfrp expression specifically in the HE Rfrp cell population, which is a cellular distinction that has not yet been analyzed using immunohistochemical data. The functional significance of the lower Rfrp levels in Ob mice is not yet known; RFRP-3 has proposed roles in several other physiological/behavioral systems beyond reproduction, such as feeding, stress, and anxiety, and the observed decreases in Rfrp levels in Ob mice may reflect RFRP-3’s involvement in these processes rather than the reproductive impairments of these animals.

Although we show a notable decrease in overall Rfrp levels in adult Ob mice of both sexes, it remains unclear if this is due to changes in direct or indirect leptin signaling to RFRP-3 cells. Rizwan et al. [56] showed minimal phosphorylation of signal transducer and activator of transcription 3 in RFRP-3 neurons after leptin treatment, ranging from ~3% in mice to 7–13% in rats, suggesting that any effects of leptin would likely be indirect. In the present study, using double-label techniques, we found direct anatomical evidence for a slightly higher degree of LepRb expression in Rfrp neurons, 15–20% in female and male mice, suggesting that some effects of leptin could in fact be directly on a subset of Rfrp neurons. Yet, based on the overall low-to-moderate percentage of total Rfrp neurons expressing LepRb, we concur with Rizwan et al., that the majority of RFRP-3 neurons in rodents are likely not directly responsive to leptin signaling. If so, the diminished Rfrp levels observed in Ob mice may reflect any of the following: (1) direct leptin signaling in only a small subset (~15–20%) of Rfrp cells, causing only those cells to change gene expression, (2) indirect leptin signaling on upstream leptin-responsive circuits that themselves directly regulate RFRP-3 neurons, and (3) influence of non-leptin metabolic signals that are secondarily altered in the obese state of Ob mice. This last possibility seems likely since Rfrp expression was normal in young juvenile Ob mice, in which leptin signaling is absent but obesity has yet to emerge. Of note, despite the observed low-to-moderate levels of LepR-Rfrp coexpression, very strong LepR expression was observed in the ARC and other areas of the same brain sections, demonstrating the robustness of LepR probe staining in our assays.

Central injections of RFRP-3 reportedly stimulate food intake [23, 24], and RFRP-3 neurons are activated by chronic mild (20%) food restriction in hamsters [25]. Moreover, a recent report demonstrated that LH secretion is not suppressed after 12 h of FD in Gpr147 knock-out mice (lacking the RFRP-3 receptor), suggesting that RFRP-3 is involved in the metabolic regulation of LH [26]. We therefore examined whether Rfrp expression levels or Rfrp neuronal activation is altered in adult female mice subjected to 12-hour FD. This short-term FD had no effect on Rfrp expression or Rfrp neuronal activation. These results are surprising, as body weight and LH levels were significantly lower after FD, reflecting effective metabolic challenge and inhibition of the reproductive system. Thus, the lower LH levels observed in our metabolically challenged females, which we hypothesized to be a direct or indirect effect of enhanced RFRP-3, appear to be decreased by some other mechanism. The previously observed increase in Rfrp neuronal activation in hamsters that were food restricted to 80% of normal diet for much longer periods of time (8 days or more [25]) may suggest that metabolic alteration of Rfrp neurons may be part of either chronic or mild nutritional stress, rather than acute, severe changes in energy availability, as in our 12-hour FD paradigm.

Over the course of postnatal development, there are drastic age-specific changes in neural Rfrp expression, especially in the late infantile and juvenile phases. Previously, we demonstrated that both the number of HE Rfrp cells and the total amount of Rfrp mRNA per cell are considerably lower at birth than on PND 10, at which time the number of LE Rfrp cells is lower than at birth [9]. Here, we determined a more detailed time-line during the first 2 weeks of life. In normal C57BL6 mice, the develop-
mental increase in HE Rfrp cells and total Rfrp mRNA appears around PND 6–8, with a peak in these measures around PND 12. This was in striking synchronous alignment with the occurrence of the postnatal leptin surge. However, using Ob mice, we found that neither the timing nor magnitude of this developmental pattern of the Rfrp population is leptin dependent. The developmental changes observed in Rfrp expression may be due to other metabolic hormones, such as ghrelin or insulin [57–59], or reproductive hormones from maturing gonads [60–63], all of which have been shown to modify gene expression in the developing hypothalamus. Identifying the cause of the dramatic Rfrp changes during development, and just as importantly, their functional significance, will be an important avenue of future inquiry.

In conclusion, the data presented here provide further insight into the regulation and development of RFRP-3 neurons in mice. We show for the first time that peripherally administered murine RFRP-3 peptide can significantly inhibit LH secretion in adult female mice, consistent with reports for other RFRP-3 variants in other species. We also show that although Rfrp neurons do not express neuropeptide Y or TRH, there does appear to be a small subpopulation of Rfrp neurons that coexpress LepRb, allowing for the possibility of direct leptin signaling in these cells. This finding is extended by the novel observation that adult Ob animals have less Rfrp expression than their WT littermates, though whether this decrease in Rfrp expression is due to direct or indirect effect of leptin signaling, or other metabolic cues associated with obesity, remains to be determined. Additionally, we demonstrate that Rfrp expression in female mice is resistant to short-term FD, despite previous reports demonstrating effects of long-term mild food restriction on RFRP-3 neurons in other species. Thus, the observed decrease in LH after short-term FD in mice is unlikely to be due to changes in RFRP-3 neurons. Lastly, we characterize the detailed developmental pattern of Rfrp expression in the rodent brain during infantile and juvenile life, and though this pattern correlates with leptin levels, we find it is independent of leptin signaling. The mechanism and physiological significance of these dramatic Rfrp changes during juvenile development remains to be determined.
