Abstract

The noise temperature of a dc SQUID coupled to a tuned input circuit
is computed using the complete quantum expression for the equilibrium noise
in the shunt resistance of each junction. At T=0, where the noise reduces
to zero-point fluctuations, the noise temperature for an optimized system
is $h\nu/k_B \ln 2$, where $\nu$ is the signal frequency. The computation is extended
to non-zero temperatures, and it is shown that a SQUID operated at 1K can
approach the quantum limit.

Recent research on dc SQUIDs has been directed toward the fabrication
of a device limited in sensitivity by intrinsic quantum mechanical noise
processes. In this Letter we present a model calculation of the noise in
the dc SQUID that involves the complete quantum expression for the equilib­
rium noise in the shunt resistance of each junction. At T=0, where the
sensitivity is limited by zero-point fluctuations in the shunt resistances,
for an optimized SQUID we find an equivalent noise energy $\epsilon/1Hz = S_\Phi/2L = h$, 
where $S_\Phi$ is the spectral density of the equivalent flux noise, and $L$ is
the SQUID inductance. When the SQUID is coupled to an optimized series-
resonant input circuit, we find the noise temperature of the amplifier to
be $T_N \approx \hbar \nu/k_B \ln 2$, where $\nu$ is the signal frequency. This noise temperature represents the uncertainty principle limit for any amplifier and thus the system operates nearly as an ideal amplifier at $T=0$. We show that by proper choice of parameters it should be possible to approach this ideal behavior with a SQUID operated at 1K.

Tesche and Clarke calculated $\epsilon/1\text{Hz}$ for a SQUID incorporating two resistively shunted Josephson junctions (RSJ) with zero capacitance assuming that the only source of noise was thermal noise in the resistive shunts. Their predictions have subsequently been found to be in reasonable accord with experimental measurements. In the absence of any rigorous calculation of the limiting voltage noise in a current-biased RSJ at $T=0$, they speculated that the ultimate sensitivity should be limited by pair shot noise in the tunnel junctions. Assuming a shot noise voltage spectral density $2eI_0 R^2$ for a junction with critical current $I_0$ and shunt resistance $R$, they found $\epsilon/1\text{Hz} \approx \hbar/2$ for an optimized SQUID. However, subsequent calculations by Koch et al. suggest that the noise in RSJ at $T=0$ is set by zero-point fluctuations in the shunt resistance rather than by any intrinsic shot noise in the junction itself. We now apply the zero-point fluctuation calculation, including the effects of junction capacitance, to the case of the SQUID.

We begin by considering the isolated symmetric SQUID. Each of the two junctions has a critical current $I_0$, capacitance $C$, and shunt resistance $R$. We introduce the dimensionless parameters $\beta_c \equiv 2\pi I_0 R^2 C/\phi_0$, $\beta \equiv 2LI_0/\phi_0$, $\kappa \equiv eI_0 R/k_B T$ and $\gamma \equiv 2\pi k_B T/I_0 \phi_0$. The phase differences across junctions 1 and 2, $\delta_1$ and $\delta_2$, and the voltage $V(t)$ across the SQUID are related to the circulating current $J(t)$ and applied flux $\phi$ by the equations
3.

\[
\frac{J}{I_0} = (\delta_1 - \delta_2 - 2\pi \phi/\phi_0)/\pi \beta, \\
V = (\delta_1 + \delta_2) \phi_0/4\pi, \\
\beta_c \frac{\delta_1^2}{I_0} \left( \frac{\phi_0}{2\pi R} \right)^2 + \delta_1 \left( \frac{\phi_0}{2\pi R} \right) = \frac{I}{2} - J - I_0 \sin \delta_1 + I_{n1}, \\
\beta_c \frac{\delta_2^2}{I_0} \left( \frac{\phi_0}{2\pi R} \right)^2 + \delta_2 \left( \frac{\phi_0}{2\pi R} \right) = \frac{I}{2} + J - I_0 \sin \delta_2 + I_{n2}.
\]

Here, \(I_{n1}\) and \(I_{n2}\) are the equilibrium noise currents generated in the shunt resistors, each with a spectral density \((2hv/R) \coth(hv/2k_BT)\), which includes zero-point fluctuations. To find the limiting performance, we first solve Eqs. (1) to (4) numerically to obtain \(\varepsilon/1\text{Hz}\) and \(T_N\) for a SQUID at \(T=0\) with \(\kappa=0.02\) \((R=40\Omega)\) and \(\beta=1\); at \(T=0\), the spectral density of the current noise in each shunt resistor reduces to \(2hv/R\). The computer techniques used were similar to those described briefly in our earlier paper. Figure 1 (a)-(f) shows the time-averaged voltage \(V\), the transfer function \(\partial V/\partial \phi\), and the noise spectral densities \(S_V\), \(S_J\), \(S_{VJ}\), and \(\varepsilon/1\text{Hz}\) vs. \(\phi\) for three values of \(\beta_c\), where \(S_V\) and \(S_J\) are the spectral densities of the voltage noise across and the current noise around the SQUID; \(S_{VJ}\) is the cross-spectral density of these two noises, and \(\varepsilon/1\text{Hz} = S_\phi/2L\), where \(S_\phi = S_V/(\partial V/\partial \phi)^2\). The current \(I\), which has the same value of \(1.63 I_0\) for all the curves, has been chosen so that the maximum in \(\partial V/\partial \phi\) always occurs near \(\phi=\phi_0/4\). In a separate investigation, we have found that this procedure produces the optimum performance. The peaks in the noise spectral densities occur at slightly different values of applied flux than the peak in \(\partial V/\partial \phi\). As \(\beta_c\) is increased from 0.25 to 1, the maximum values of \(\partial V/\partial \phi\) and \(S_V\), \(S_J\), and \(S_{VJ}\) all increase markedly. However, the minimum values of \(\varepsilon/1\text{Hz}\) are remarkably close to each other, reflecting the fact that \((\partial V/\partial \phi)^2\) and \(S_V\) increase almost proportionately as \(\beta_c\) is changed with \(R\) held constant.
The minima in $\epsilon/1\text{Hz}$, about $h$ in all three cases, are much broader with respect to the applied flux than the peaks in $\partial V/\partial \phi$ and the noise spectral densities.

The quantity $\epsilon/1\text{Hz}$ is a convenient parameter for comparing the performance of isolated SQUIDS, but does not completely specify the sensitivity of the device. In practice, the SQUID must be coupled to an input circuit, and one must take into account not only $S_V$, but also $S_J$ and $S_{VJ}$. The current noise of the SQUID couples back to the input coil, producing a real voltage noise at the input terminals, while the voltage noise of the SQUID can be regarded as an effective noise referred to the input. In ref. 6 it was shown that the tuned input circuit shown in Fig. 2 has a higher sensitivity than an untuned circuit. For a given source resistance $R_i$, the values of $L_i$ and $C_i$ have been optimized$^6$ for a signal frequency $\nu << 2eV/h$. From Eqs. (15) and (16) of ref. 6, it is straightforward to show that the SQUID introduces a total effective voltage noise referred to the input terminals of the voltmeter with a spectral density

$$S_V(\nu) = \frac{4\pi R_i}{\partial V/\partial \phi} (S_V S_J - S_{VJ}^2)^{1/2}. \quad (5)$$

We define the quantity $n(\nu)^{s}$ as the effective mean photon power per hertz in the input circuit due to intrinsic SQUID noise. Thus

$$n(\nu)^{s} = \pi (S_V S_J - S_{VJ}^2)^{1/2}/h(\partial V/\partial \phi). \quad (6)$$

In Fig. 1(g), we plot $n(\nu)^{s}$ vs. $\phi$. We see that for $\beta_C = 0.25$ and 0.5, $n(\nu)^{s}$ has the minimum value of $\nu^{1/2}$, whereas for $\beta_C = 1$, the minimum has a somewhat higher value. Thus, for $\beta_C = 0.25$ and 0.5, an optimized tuned voltmeter at $T=0$ has a mean input noise due to the intrinsic SQUID noise of $1/2$ photon
at the measurement frequency.

The intrinsic noise can be expressed alternatively as a noise temperature.\textsuperscript{7,8} At a signal frequency $\nu$, we add the SQUID noise in the input circuit, $\omega \nu / 2$, to the zero-point fluctuations of the input resistor, $\hbar \nu / 2$, and equate the sum to the thermal noise power per Hz available from the resistor at an effective temperature $T_N$, namely $\hbar \nu / [\exp(\hbar \nu / k_BT_N) - 1]$.

We thus obtain

$$T_N \approx \frac{\hbar \nu}{k_B \ln 2}$$

the optimum value for any linear amplifier.\textsuperscript{7}

We now consider briefly the experimentally realistic case $T > 0$. In Table I we list values of $\omega V / \dot{\phi}$, $\epsilon / \nu$Hz and $n(s)$ for a SQUID with an inductance of 1pH and a capacitance at 0.5pF per junction (corresponding to a junction area of about $10\mu m^2$), for specified values of $T$, $\beta$, $I_0$, $\beta_c$, and $R$. We also list $\kappa V / I_0 R$, the parameter characterizing the relative importance of the quantum and thermal noise sources, and $\Delta \Phi / \Phi_0$, a measure of the applied flux over which the quoted sensitivity can be obtained. For the computations at 4.2K we used the classical limit $4k_BT/R$ for the spectral density of the current noise in each shunt, whereas at the lower temperatures we used the full expression $(2\hbar \nu / R) \coth (\hbar \nu / 2k_BT)$. At 4.2K, we find for the fixed values of SQUID inductance and junction capacitance chosen, the best $\epsilon / \nu$Hz occurs at $\beta \approx \beta_c \approx 1$. At 4.2K, the values of $\epsilon / \nu$Hz range from about $3\hbar$ to $11\hbar$, while the values of $n(s)$ range from about 4.5 to 9. It is interesting to note that the lowest values of $\epsilon / \nu$Hz do not necessarily correspond to the lowest values of $n(s)$ due to the effects of current noise. We have
also computed the sensitivity at $T=0.9K$ and $0.45K$ for the values $\beta=\beta_c=1$, and find $n(s)=2.0$ and $1.5$, respectively. It is interesting to note that the SQUID approaches the quantum limit when $kV/I_R>1$, as we would expect from our analysis of the single junction. As one goes to lower temperatures, the range of applied flux, $\Delta\phi/\phi_0$, over which the best sensitivity is obtained narrows from 0.005 at 4.2K to 0.001 at the lower temperatures.

In conclusion, we have shown that at $T=0$ a dc SQUID coupled to a tuned input circuit has a noise temperature of $\sim kT/\Delta\phi$, corresponding to an intrinsic photon power per Hz of $\sim h\nu$, when the parameters are properly optimized. At a temperature of 1K, one should be able to achieve a photon power per Hz of about $2h\nu$, using junctions with a critical current density of $10^8 A/m^2$. Junctions with a smaller area and a higher critical current density should enable one to achieve an even better performance, provided that heating or other non-equilibrium effects do not become important.

The near ideal performance for a given bias current is obtained over a relatively narrow range of flux, typically $10^{-3}$ to $10^{-2}\phi_0$. However, since the flux noise is typically $10^{-8}\phi_0 Hz^{-1/2}$, the dynamic range of the amplifier can still be considerable, at least $10^5$ in a unit bandwidth. The limited working range of the SQUID makes it most attractive as a small-signal amplifier, without flux-modulation or negative feedback, although operation in a flux-locked loop with near-ideal sensitivity may not be out of the question. In our calculations we have entirely neglected the contributions of $1/f$ noise which will, of course, degrade the performance at low
frequencies. On the other hand, the quoted performance should be obtainable up to high frequencies, say 1/10 of the Josephson frequency or about 10 GHz for the devices listed in Table I.

Finally, we remark that it may be difficult to achieve a high coupling coefficient, $\alpha$, between a SQUID with an inductance as low as 1pH and an input inductance large enough to be useful in many applications. In principle, since $\alpha$ does not appear in Eq. (6), a low coupling efficiency does not have a deleterious effect on the noise/temperature, but, in practice, a low value of $\alpha$ may lead to undesirable values of $R_i$ and/or $C_i$. However, if one were to reduce the junction area to $0.1\mu m^2$, one could increase $L$ to the more useful value of 100pH and still achieve comparable performances to those listed in Table I.
