COAL LIQUEFACTION RESEARCH

Principal Investigator: Heinz Heinemann

Lawrence Berkeley Laboratory

University of California

Berkeley, CA 94720

This work was supported by the Assistant Secretary for Fossil Energy, Office of Coal Research, Liquefaction Division of the U. S. Department of Energy under Contract W-7405-Eng-48 through the Pittsburgh Energy Technology Center, Pittsburgh, PA.

This manuscript was printed from originals provided by the author.
This project is aimed at examining the differences between Fischer-Tropsch reactions carried out in a slurry reactor on the one hand and in a fixed bed reactor on the other hand. As outlined in our previous report, there are two differences between slurries and fixed beds: 1) in a slurry reactor, less catalyst deactivation is observed, even at low H₂/CO ratios. 2) The product distributions are different: Higher relative amounts of heavy products are produced in the slurry. Both of these differences have been confirmed experimentally. An earlier phase of this project was concerned with temperature control in the reactors. (See report of July 10, 1981). The present phase centers on an investigation of mass transport phenomena. We are engaged in research on two levels: experimental and computational.

A. Experimental work

The experiments have been aimed at measuring mass transfer coefficients and reaction kinetics, which will be used in a model of the slurry reactor. Obtaining data has been difficult, for two mechanical reasons. First, the flow controllers have not been functioning properly, and second, the catalyst tends to cake, and sometimes plug the reactor. Experiments with a glass column, the geometry of which is similar to that of the pressure slurry reactor have led to the design of baffles that break up clumps of catalyst.

The data we have taken allow us to draw some conclusions about the Fischer-Tropsch slurry system. Using the apparatus described in the report of September 26, 1980, the rates of production of CO₂ and hydrocarbons through C₁₀ were measured as a function of H₂/CO ratio and temperature. The catalyst was subjected to six days of reduction under 10 atm of hydrogen at a space velocity of 80 cm³/min-g catalyst. The catalyst loading was 0.125 of catalyst/kg slurry liquid. The data discussed here were taken over a ten-day period. A schedule of the run is shown in Table 1. After the first 50 hours, no deactivation was observed. The data shown were all taken during steady state operation. Table 2 shows rates of production of CO₂ and hydrocarbons through C₁₀ as a function of temperature, at H₂/CO = .96 and P = 10 Atm. If no water is produced, the rate at which carbon is incorporated into hydrocarbons will be equal to the rate of CO₂ production. The total rate of carbon incorporation through C₁₀ is shown in the last column in Table 2. If this rate is lower than the rate of CO₂ production, some of the
CO is consumed to make other products. The fate of this CO is not known. It may form surface carbon; it may react with the iron to make iron carbide; it may react with the slurry liquid; or it could make alcohols, which were present in small amounts. It is also possible that the CO is converted to heavier hydrocarbons, which stay in the slurry liquid. If the rate of carbon incorporation into hydrocarbons is greater than the rate of CO₂ production, hydrogen must react on the catalyst surface to produce water. From the numbers in Table 2, it can be seen that at low temperature, water is produced. This is consistent with the equilibrium behavior of the water gas shift reaction: low temperature favors the production of water. (1). As temperature increases, the rate of consumption of CO for other products increases. This is consistent with McKee's (2) data on fixed bed reactors, which showed that carbon formation increased with temperature.

In Figure 1, activation energy plots are shown for CO₂, CH₄, and C₂H₄. All of the curves show activation energies that decrease as temperature increases, although they remain relatively high. (31 K cal for CO₂) This is an indication that mass transfer is starting to affect the rate of reaction. The mass transfer resistance appears to be at the gas-liquid interface: Calculations based on published correlations for kₐ (3) and the measured rate of reaction at 300°C predict a slight concentration difference between the gas-liquid interface and the catalyst surface. Further, calculations based on the measured rate, using the correlation presented by Satterfield (4), show that under the conditions used, the reaction is far from an internal diffusion limited regime.

Figure 2 shows the product distribution as a function of temperature. The changes in product distribution, while not large, are consistent with other work in fixed beds. Cₙ for a given n, decreases as temperature increases; light products are favored at high temperature.

Rates of reaction as a function of H₂/CO ratio are shown in Table 3. Again, the total rate of carbon consumption is shown. In every case, a significant amount of CO is reacting to produce something other than C₁ through C₁₀ hydrocarbons. The fraction f of CO that goes to other products is given by $f = 1 - \sum \frac{nRcn}{R_{CO2}}$

f is not a strong function of H₂/CO; however, as we might expect, f increases as the H₂/CO ratio decreases.

The product distribution as a function of H₂/CO ratio is also shown in Figure 3. As the H₂/CO ratio increases, the curve Cₙ vs. n becomes steeper; lighter products are favored.

Note that the rates of reaction at 300°C and H₂/CO = .88 are significantly different from those at H₂/CO = .96 and 300°C. This is believed to result from a higher degree of carbidization at H₂/CO = .96. As shown in Table 1, the data at H₂/CO = .88 was taken after a long period of
running at high $H_2/CO$ ratio. The higher value for $f$ at $H_2/CO = .88$ supports this hypothesis: since the catalyst is less carbided, the rate of carbon consumption for carbiding increases.

B. Computational Work

A model for the slurry reactor has been developed, assuming plug flow in the gas, and a well-stirred liquid phase. Such a model gives rise to a differential mass balance equation for each component in the gas phase, an overall balance for the gas phase, and in integral balance for each component in the liquid phase. In the equations presented, all variables are defined in the nomenclature section on page 9.

The gas phase balance is:

$$\frac{-dW_i}{dz} = k_L a_i \left( \frac{C_i}{H_i} - C_{iL} \right)$$  \hspace{1cm} (1)

The overall balance comes from summing equation (1) over all components:

$$- \frac{dW}{dz} = \sum_{i=1}^{n} \frac{k_L a_i}{C_{TOT}} \left( \frac{C_i}{H_i} - C_{iL} \right)$$  \hspace{1cm} (2)

The liquid phase balance can be written:

$$Q_L C_{iL} + \int_0^{V_R} R_L a_i \left( \frac{C_i}{H_i} - C_{iL} \right) dV_R - R_i V_R = 0$$  \hspace{1cm} (3)

Rearranging the integral yields:

$$- Q_L C_{iL} + \int_0^{V_R} R_L a_i \left( \frac{C_i - C_{iL}}{H_i} \right) dV_R - R_i V_R = 0$$  \hspace{1cm} (4)

where $\overline{C_i} = \frac{1}{L} \int_0^L C_i \, dz$

these equations are solved in the following manner:

1) Guess $C_{iL}$
2) Solve the gas phase mass balances
3) Evaluate $\overline{C_i}$
4) Check to see if the liquid balance is satisfied.
5) If not, go to 1) and guess a new $C_{iL}$.

A Fortran program has been written to find this solution, and has been tested on the simple case: $2\text{ CO} + 2\text{H}_2 \rightarrow \text{CO}_2 + \text{CH}_4$, where the reaction is assumed to be first order in $\text{H}_2$ and zero order in $\text{CO}$. The differential equation solvers on file at U.C. is used to solve the gas phase balances, and the regula falsi method is used to iterate $C_{iL}$. The regula falsi method has been found to converge.

The work proposed in the immediate future remains, for the most part, unchanged. We will continue to look at mass transfer effects, and the extent to which recombination occurs: both can have an effect on deactivation and product distribution. However, the work presented here may indicate that deactivation is different in the slurry reactor, regardless of heat or mass transfer. The presence of the slurry liquid may change the course of the reaction on the catalyst surface.

NOMENCLATURE

a  Bubble area per reactor volume, cm$^{-1}$

$C_i$  Gas phase concentration of component i, moles/cm$^3$

$C_{iL}$  Liquid phase concentration of component i, moles/cm$^3$

$C_T$  Total gas phase concentration, moles/cm$^3$

$H_i$  Henry's law constant for component i, $\frac{\text{moles/cm}^3}{\text{moles/cm}^3}$

$k_{Li}$  Mass transfer coefficient for component i from gas-liquid interface to bulk liquid, cm/sec

L  Height of the reactor, cm

$R_i$  Rate of consumption of component i per reactor volume, moles/sec-cm$^3$

$Q_L$  Volumetric flow rate of liquid, cm$^3$/sec

$V_R$  Volume of the reactor

$k_i$  Rate constant, $\frac{\text{moles i}}{\text{cm}^3\text{sec} \text{ (moles H}_2\text{)}^{-1}}$

z  Position in the reactor, cm
