April 11, 1955

The nuclide $^{99}_{254}$ has previously been reported$^1,^2$ and found to decay$^2,^3$ with a half-life of 36 hours by emission of $\beta^-$ particles. Further investigation has revealed the existence of another isomer of $^{99}_{254}$ which decays almost entirely by emission of alpha particles. The 36-hour isomer has been found to exhibit electron-capture branching to produce $^{254}_{\text{Cf}}$.

1. The long-lived isomer -- Samples of the 20-day 6.6-Mev alpha emitting $^{99}_{253}$ subjected to neutron bombardment were shown by alpha pulse analysis to contain a nuclide emitting $6.44 \pm 0.01$ Mev alpha particles. This new alpha radioactivity showed no decrease in intensity during 3 months, so that the nuclide responsible for it must have a half-life longer than about 2 years.

Chemical purification of the $^{99}_{253}$ by the method of ion-exchange elution, using Dowex-50 cation resin and ammonium $\alpha$-hydroxy-isobutyrate as eluant$^4$ showed that the 6.44-Mev alpha emitter could not be separated from element 99.

Its assignment, based on the systematics of alpha radioactivity,$^5,^6$ was most logically to mass 254. This assignment was confirmed by collecting recoil nuclei from a very thin sample of the new alpha emitter. These daughter nuclei were shown to decay, by emission of
particles, with a half-life of approximately 3 hours. This radiation is characteristic of Bk$^{250}$. 7

The absence of any 7.2-Mev alpha particles of 100$^{254}$ 1, 2, 3, 8 in equilibrium with this long-lived isomer of 99$^{254}$ shows that the partial half-lives of the latter species for both $\beta^-$ decay and isomeric transition to the 36-hour isomer are more than 100 times longer than the alpha half-life. It is perhaps more likely that the 36-hour isomer is the metastable state, and it will be convenient provisionally to refer to it as 99$^{254}$m.

2. Electron capture in 99$^{254}$m. --Preliminary experiments 9 showed that a californium isotope decaying by spontaneous fission, with no detectable emission of alpha particles, grew into very carefully purified samples containing 99$^{253}$, 99$^{254}$, 99$^{254}$m, and 99$^{255}$. The californium exhibited a half-life of 85 ± 15 days. This observation has since been repeated and confirmed with much larger amounts of activity.

The californium isotope responsible for such a short-lived spontaneous fission decay is most likely of even mass, and is therefore probably Cf$^{254}$, since Cf$^{250}$ and Cf$^{252}$ are already known. 7, 10, 11 Some Cf$^{256}$ might have been formed by electron capture decay of the (unknown) nuclide 99$^{256}$, which might have been present in the sample. However, 99$^{256}$ is expected to be short-lived, 12 and any Cf$^{246}$ produced by its electron-capture decay would have been removed in the initial purification of the 99 sample. Samples containing only 99$^{253}$ and 99$^{254}$ exhibit only a very small spontaneous fission activity. The Cf$^{254}$ must therefore grow from the 36-hour 99$^{254}$m, by the electron-capture process, and not from the 99$^{254}$. The amount of Cf$^{254}$ produced by a known amount of 99$^{254}$m gave a value of 1000 for the ratio of $\beta^-$ decay to electron capture.

This work was performed under the auspices of the U.S. Atomic Energy Commission.
