PRL 104, 151802 (2010) PHYSICAL REVIEW LETTERS week ending 16 APRIL 2010
Charged-lepton flavor-violating processes are unobservable in the standard model, but they are predicted to be enhanced in several extensions to the standard model, including supersymmetry and models with leptoquarks or compositeness. We present a search for such processes in a sample of $99 \times 10^6 \gamma (\tau \nu \nu)$ decays and $117 \times 10^6 \gamma (\tau \nu \nu)$ decays collected with the BABAR detector. We place upper limits on the branching fractions $\mathcal{B}(\gamma (n\tau \nu) \rightarrow e^- \tau ^-) \gamma (n\tau \nu) \rightarrow \mu ^- \tau ^-)$ ($n = 2, 3$) at the $10^{-6}$ level and use these results to place lower limits of order 1 TeV on the mass scale of charged-lepton flavor-violating effective operators.

In the original formulation of the standard model (SM) in which neutrinos are massless, lepton flavor is an accidentally conserved quantum number. The extension of the SM to include neutrino masses introduces oscillations between the neutrino flavors, which violate this conservation law. However, SM processes involving charged-lepton flavor violation (CLFV) remain unobservable because they are suppressed by the quantity \( \Delta m^2 / M_W^2 \lesssim 10^{-48} \) [1–3]. Here \( \Delta m^2 \) is the difference between the squared masses of neutrinos of different flavor and \( M_W \) is the charged weak vector boson mass. Hence, CLFV represents an unambiguous signature of new physics (NP) [4–7]. Many extensions to the SM, including supersymmetry and models with leptoquarks or compositeness, predict an enhancement in the sensitivity. There have been considerable efforts in searches for CLFV in decays of particles such as \( e \) and \( \tau \) leptons and \( B \) and \( K \) mesons, but CLFV in the \( \nu \) sector remains relatively unexplored [8]. By using unitarity considerations, limits on CLFV \( \tau \) branching fractions [9] have been used to place indirect limits on CLFV \( Y \) branching fractions at the \( \mathcal{O}(10^{-3}) \) level [10]. In this Letter we describe a search for CLFV \( Y \) decays, which is 1000 times more sensitive than these indirect limits, using data collected with the \( \text{BABAR} \) detector at the PEP-II \( B \) factory at SLAC National Accelerator Laboratory. Since these decays are in general mediated by new particles produced off shell in loops, their measurement probes mass scales up to the TeV scale, far exceeding the \( 10 \) GeV \( \mu \)-pair production, for which the final state consists of leptonic and hadronic \( \tau \)-decay modes for the \( Y(nS) \rightarrow e^\pm \tau^\mp \) and \( Y(nS) \rightarrow \mu^\pm \tau^\mp \) searches, hereafter referred to as the leptonic and hadronic \( e\tau \) and \( \mu\tau \) channels. The main source of background to our events comes from \( \tau \)-pair production, for which the final state particles are the same as for the signal. There is a background contribution to the \( e\tau \) channels from Bhabha events in which one of the electrons is misidentified, and to the \( \mu\tau \) channels from \( \mu \)-pair events in which one of the muons is misidentified or decays in flight, or an electron is generated in a material interaction. An additional background consisting of events with multiple pions and possible additional photons (“\( \pi \)-hadron background”), in which a charged pion is misidentified as a lepton and the remaining particles pass the selection criteria for the \( \tau \)-decay products, contributes to the hadronic \( e\tau \) and \( \mu\tau \) channels.

In order to reduce background, we first apply requirements common to all the decay modes and then a channel specific selection. All events are required to have exactly two tracks of opposite charge, both consistent with originating from the primary interaction point and with opening angle greater than \( 90^\circ \). To suppress Bhabha and \( \mu \)-pair backgrounds, we require that \( M_{\text{vis}} / \sqrt{s} < 0.95 \), where \( M_{\text{vis}} \) is the invariant mass of the sum of the 4-vectors of the two charged particles and of all photon candidates in the event. To ensure that the missing momentum is not pointing toward the holes in the detector near the beam line, we require that \( \cos(\theta_{\text{lab}}^{\text{miss}}) < 0.9 \) and \( \cos(\theta_{\text{c.m.}}^{\text{miss}}) > -0.9 \), where \( \theta_{\text{lab}}^{\text{miss}} \) (\( \theta_{\text{c.m.}}^{\text{miss}} \)) is the polar angle of the missing momentum in the lab (c.m.) frame. To suppress two-photon processes, we require that \( (p_1 + p_2)^2 / (\sqrt{s} - |p_1| - |p_2|) > 0.2 \), where \( p_1 \) and \( p_2 \) are the momenta of the primary lepton and...
The channel specific selection classifies events into one of the four signal channels. The momentum of the primary candidate must deposit at least 50 MeV in the EMC and C22 to suppress Bhabha and x

that a particle of type x

peaks at m/C26

final states are dominated by the decays

Since these τ decays to hadronic τ-decay channels, in order to suppress Bhabha and μ-pair backgrounds. A photon veto are used to identify charged pions. The particle mis-identification efficiencies are O(10^{-6}) (μ → e), O(10^{-5}) (e → μ), and O(10^{-1}) (ℓ → π), where x → y indicates that a particle of type x is misidentified as a particle of type y. Because of the large ℓ → π misidentification efficiencies, it is necessary to require the presence of at least one neutral pion in the hadronic τ-decay channels, in order to suppress Bhabha and μ-pair backgrounds. A photon candidate must deposit at least 50 MeV in the EMC and have a shower profile consistent with that expected from an electromagnetic shower. All pairs of photons with an invariant mass between 0.11 and 0.16 GeV are selected as neutral pion candidates.

The momentum of the primary lepton normalized to the beam energy is required to satisfy x = |p_{L}|/E_{B} > 0.75. For the hadronic τ-decay channels, the current of the τ-daughter charged pion is required to satisfy |p_{S}|/E_{B} < 0.8. Since these τ decays to hadronic final states are dominated by the decays τ^{±} → ρ^{±}ν_{τ} and τ^{±} → a_{1}^{±}ν_{τ}, the masses of the π^{±}π^{0} and π^{±}π^{0}π^{0} systems are required to be consistent with the masses m_{π} = 0.77 GeV and m_{a_{1}} = 1.26 GeV, respectively, where the requirement on the π^{±}π^{0}π^{0} system mass is included only if there are two neutral pions in the event. In order to suppress Bhabha events in which an electron is misidentified as a muon, for the leptonic eτ channel the τ-daughter muon is required to penetrate deeply into the muon detector. In order to suppress μ-pair events in which the tracks are back to back, for the leptonic μτ channel the tracks are required to satisfy Δφ < 172°, where Δφ is the difference between the track azimuthal angles. After including all selection requirements, typical signal efficiencies determined from MC simulations are (4–6)% [20], including the τ-decay branching fractions. The typical number of events passing the selection criteria is (10–15) \times 10^{3} for Y(2S) data and (20–30) \times 10^{3} for Y(3S) data, depending on the signal channel. These yields are consistent with background expectations from MC simulations.

After selection an unbinned extended maximum likelihood fit is performed to the x distribution. The signal peaks at x ≈ 0.97, while the τ-pair background x distribution is smooth and approaches zero as x → x_{max}, where x_{max} = 0.97 is the effective kinematic end point for the lepton momentum in the decay τ^{±} → ℓ^{±}ν_{τ}ν_{τ}, boosted into the Y(nS) rest frame. The x distributions for the Bhabha or μ-pair backgrounds have a peaking component near x = 1, about (2.5–3)σ_{x} above the signal peak, where σ_{x} = 0.01 denotes the detector x resolution. The x distribution for the π-hadron background is smooth and falls off sharply near x = x_{max}. Probability density functions (PDFs) for signal, τ-pair, Bhabha or μ-pair, and π-hadron backgrounds are determined as discussed below, and a PDF consisting of the sum of these components weighted by their yields is fitted to the data for each signal channel, with the yields of the components allowed to vary in the fit.

The PDFs for signal and Bhabha or μ-pair backgrounds are obtained from fits to the x distributions of MC events. The signal is modeled by a modified Gaussian with low- and high-energy tails, hereafter referred to as a double Crystal Ball [21] function, which peaks near x = 0.97. The Bhabha and μ-pair backgrounds have a threshold component truncating near x = 1, which is modeled by an ARGUS distribution [22], and a peaking component near x = 1, which is modeled by a Gaussian function. The π-hadron PDF is determined from data by modifying the selection to require that the primary lepton is instead identified as a charged pion. The resulting binned x distribution is scaled by the probability for pions to be misreconstructed as charged leptons, as measured in data, to yield a binned PDF for the π-hadron background. The yield of this component is fixed in the maximum likelihood fit and an uncertainty of 10% is assessed, based on the estimated contributions of additional background sources such as K hadron. The τ-pair background is modeled by the convolution of a polynomial, which vanishes above the kinematic end point x_{max}, and a detector resolution function. The detector resolution function is modeled by a double Crystal Ball function whose shape is extracted from τ-pair MC events. Since the signal peaks in the region near the kinematic end point of the τ-pair background x distribution, the signal yield depends strongly on x_{max}, which must therefore be extracted from data. The value of this parameter is extracted from fits to the Y(4S) data control sample and corrected for differences in the decay kinematics at the Y(4S) vs Y(nS) resonances. The polynomial shape parameters, which are not strongly correlated with the signal yield, are allowed to vary in the fits to Y(nS) data.

To validate the fit procedure, we perform fits to data control samples in order to verify that signal yields consistent with zero are obtained. The Y(4S) data are divided into samples that are chosen to be comparable in size to the Y(2S) and Y(3S) data samples. The off-peak data and the 1.2 fb^{-1} of Y(3S) data constitute additional data control samples. Results consistent with zero signal yield are obtained for all signal channels in these data control
samples. To assess the possible bias in the fit procedure, several hundred simulated experiments are produced with the generated signal yield fixed to the larger of the value extracted by the fit to Y(nS) data, or zero. The bias is consistent with zero within the uncertainty of 0.2–0.7 events, depending on the signal channel.

The branching fraction \( \mathcal{B} \) is calculated from the extracted signal yield \( N_{\text{sig}} \) according to \( \mathcal{B} = N_{\text{sig}}/(\epsilon_{\text{sig}} N_{Y(nS)}) \), where \( \epsilon_{\text{sig}} \) is the signal selection efficiency and \( N_{Y(nS)} \) is the number of collected \( Y(nS) \) decays. The dominant systematic uncertainties in the signal yields, which arise from uncertainties in the PDF shapes, are determined by varying the shape parameters while taking into account the correlations between them. This uncertainty is 3–10 events depending on the signal channel, and the largest contribution is due to the uncertainty in the kinematic end point parameter \( x_{\text{max}} \). To assess the uncertainty in the signal efficiency, we take the relative difference between the yields for data and MC events from a portion of the sideband of the \( x \) distribution defined by 0.8 < \( x \) < 0.9, which is dominated by \( \tau \)-pair events. This difference is due to particle identification, tracking, trigger, and kinematic selection efficiency uncertainties. There is an additional small uncertainty in the signal efficiencies due to the finite statistics of the signal MC samples, as well as an uncertainty arising from the uncertainties in the \( \tau \) branching fractions [12]. The total signal efficiency uncertainties are (2–4)\%, depending on the signal channel. The uncertainty on the number of collected \( Y(nS) \) decays is approximately 1\%. There is also an uncertainty resulting from a correction in the signal yield which is performed to compensate for primary leptons whose momentum is poorly measured. These particles populate a broad momentum range and some fall in the signal region defined as the interval within \( \pm 1.5\sigma \) of the signal peak. The number of these events is estimated using \( \tau \)-pair MC simulation, and scaled by the relative difference between the yields of data and MC Bhabha (\( \mu \)-pair) control samples for the \( Y(nS) \rightarrow e^{\pm}\tau^{\mp}[Y(nS) \rightarrow \mu^{\pm}\tau^{\mp}] \) channels. The expected contributions are subtracted from the signal yields extracted by the fit and an uncertainty of 100\% times the correction is assessed. The corrections are approximately three events [five events] for the \( Y(2S) \rightarrow \mu^{\pm}\tau^{\mp}[Y(3S) \rightarrow \mu^{\pm}\tau^{\mp}] \) channels and less than 1 event for the \( Y(nS) \rightarrow e^{\pm}\tau^{\mp} \) channels.

The maximum likelihood fit results for a sample channel are displayed in Fig. 1, and the fit results for all channels are available in [20]. After including statistical and systematic uncertainties, the extracted signal yields for all channels are consistent with zero within \( \pm 1.8\sigma \). We conclude that no statistically significant signal is observed and determine 90\% confidence level (C.L.) upper limits (UL) using a Bayesian technique, in which the prior likelihood is uniform in \( \mathcal{B} \) and assumes that \( \mathcal{B} > 0 \). The resulting ULs, summarized in Table I, are \( O(10^{-6}) \) and represent the first constraints on \( \mathcal{B}(Y(nS) \rightarrow e^{\pm}\tau^{\mp}) \). These results improve the sensitivity by factors of 3.7 and 5.5, respectively, with respect to the previous ULs on \( \mathcal{B}(Y(2S) \rightarrow \mu^{\pm}\tau^{\mp}) \) and \( \mathcal{B}(Y(3S) \rightarrow \mu^{\pm}\tau^{\mp}) \) [8].

FIG. 1 (color online). Maximum likelihood fit results for the leptonic \( e\tau \) channel in \( Y(3S) \) data. In the inset, the red dotted line represents the signal PDF, the green dashed line represents the sum of all background PDFs, and the solid blue line represents the sum of these components. The inset shows a close-up of the region 0.95 < \( x \) < 1.02. The top plot shows the normalized residuals (data – fit)/\( \sigma_{\text{data}} \) (pull).

Our results can be used to constrain NP using effective field theory. The CLFV \( Y(nS) \) decays may be parametrized as an effective \( b\bar{b}e^{\pm}\tau^{\mp} \) four-fermion interaction given by [8]

\[
\Delta \mathcal{L} = \frac{4\pi\alpha\ell_{\mu}}{\Lambda_{\tau}^2}[\tilde{\Gamma}_{\mu}\tau(b\bar{b})(\gamma\mu)b],
\]

where \( \Gamma_{\mu} \) is a vector or an axial current or their combination, \( \alpha_{\ell_{\mu}} \) and \( \Lambda_{\tau} \) are the NP coupling constant and mass scale, respectively. This allows the following relation to be derived [23,24]:

\[
\frac{\alpha_{\ell_{\mu}}^2}{\Lambda_{\tau}^2} = \frac{\mathcal{B}(Y(nS) \rightarrow \ell^{\pm}\tau^{\mp})}{\mathcal{B}(Y(nS) \rightarrow \ell^{+}\ell^{-})(M_{Y(nS)})^2} = 2q_{\mu}^2\alpha^2.
\]

Here \( q_{b} = -1/3 \) is the charge of the \( b \) quark, \( \alpha \equiv \alpha(M_{Y(nS)}) \) is the fine structure constant evaluated at the \( Y(nS) \) mass, and we use \( \mathcal{B}(Y(2S) \rightarrow \ell^{+}\ell^{-}) = (1.91 \pm 0.16) \times 10^{-2} \) and \( \mathcal{B}(Y(3S) \rightarrow \ell^{+}\ell^{-}) = (2.18 \pm 0.14) \times 10^{-2} \) [12]. Using these values and taking

TABLE I. Branching fractions and 90\% C.L. ULs for signal decays. The first error is statistical and the second is systematic.
FIG. 2 (color online). Excluded regions of effective field theory parameter spaces of mass scale $\Lambda_{\tau\tau}$ versus coupling constant $\alpha_{\tau\tau}$. The dashed blue line is derived from $Y(2S)$ results only, the solid red line is derived from $Y(3S)$ results only, and the solid black line indicates the combined results. The yellow shaded regions are excluded at 90% C.L.

into account the uncertainty in $\mathcal{B}(Y(nS) \rightarrow \ell^+ \ell^-)$, we determine the likelihood as a function of the quantity $\alpha_{\tau\tau}^2/\Lambda_{\tau\tau}^4$, and extract the 90% C.L. UL using the same Bayesian method as above. We use these results to exclude regions of the $\Lambda_{\tau\tau}$ vs $\alpha_{\tau\tau}$ parameter spaces as shown in Fig. 2. Assuming $\alpha_{\tau\tau} = \alpha_{\mu\tau} = 1$, these results translate to the 90% C.L. lower limits $\Lambda_{\tau\tau} > 1.6$ TeV and $\Lambda_{\mu\tau} > 1.7$ TeV on the mass scale of NP contributing to CLFV $Y(nS)$ decays, which improve upon the previous lower limit on $\Lambda_{\mu\tau}$ [8].

We are grateful for the excellent luminosity and machine conditions provided by our PEP-II colleagues, and for the substantial dedicated effort from the computing organizations that support BABAR. The collaborating institutions wish to thank SLAC for its support and kind hospitality. This work is supported by DOE and NSF (U.S.A.), NSERC (Canada), CEA and CNRS-IN2P3 (France), DFG (Germany), INFN (Italy), FOM (The Netherlands), NFR (Norway), MES (Russia), MEC (Spain), and STFC (United Kingdom). Individuals have received support from the Marie Curie EIF (European Union) and the A.P. Sloan Foundation.
