CHARGE ASYMMETRY IN THE DECAY $K_L^0 \rightarrow \pi\mu\nu$

Lawrence Berkeley Laboratory
University of California
Berkeley, California 94720

July 1972

ABSTRACT

If $\Gamma_{\pm} = \text{Rate}(K_L^0 \rightarrow \pi^{\pm}\mu^{\pm}\nu)$, the $K_L^0$ charge asymmetry is

$$\delta = (\Gamma_+ - \Gamma_-)/(\Gamma_+ + \Gamma_-).$$

This number has been measured to be $(6.0 \pm 1.4) \times 10^{-3}$ at the Lawrence Berkeley Laboratory's Bevatron. The error is meant to be interpreted as one standard deviation and contains a major systematic contribution. Large corrections were made in order to exclude neutron-induced background events and to correct for the range difference between $\mu^+$ and $\mu^-$. The meaning of the possible difference between muonic and electronic charge asymmetries is discussed.
I. INTRODUCTION

The charge asymmetries in the semileptonic decays $K_L^0 \rightarrow \pi^\mp l^\pm \nu$ are the only known manifestations of CP violation aside from the decays $K_L^0 \rightarrow \pi \pi$. Assuming CPT invariance and that the semileptonic decays proceed by first-order weak interactions only, it is possible to relate the charge asymmetries to $\epsilon$, the CP mixture parameter of the neutral K-meson states, and to $x_l$, the $\Delta S = \Delta Q$ violation parameter. \[ \delta_l = (\Gamma_+ - \Gamma_-)/(\Gamma_+ + \Gamma_-) = 2 \Re \epsilon F_l \]

\[ F_l = (1 - |x_l|^2)/|1 - x_l|^2. \]

Here $\Gamma_\pm$ is the rate for decay to $\pi^\pm l^\pm \nu$ ($l$ is either a muon or an electron). If the $\Delta S = \Delta Q$ rule holds in weak interactions, $F_l$ is equal to 1 and $\Re \epsilon = (\delta_l/2)$.

The study of the $K_{\mu 3}^0$ charge asymmetry separately from the $K_{e 3}^0$ charge asymmetry is interesting for two reasons. First, the measurement techniques and hence the sources of possible systematic errors are quite different in the two cases; second, due to the factor $F_l$, the two charge asymmetries can differ. Such a difference would not necessarily violate $\mu - e$ universality because $F_l$ could depend on the lepton mass, for example through the well-known presence of the $f_-$ form factor, which is important only in the $K_{\mu 3}^0$ decay. A difference of $F_l$ from 1 would, however, necessarily indicate a violation of the $\Delta S = \Delta Q$ rule.

We report a new measurement of the muonic charge asymmetry. The result of this experiment should be compared to the previous result for the $K_{\mu 3}^0$ asymmetry, \cite{4} the best value of the $K_{e 3}^0$ asymmetry, \cite{5} and the prediction of the superweak theory. \cite{6}
this experiment : \[ \delta_\mu = (6.0 \pm 1.4) \times 10^{-3} \]

previous \( K^0 \) : \[ \delta_\mu = (5.7 \pm 1.7) \times 10^{-3} \]

best value \( K^0 \) : \[ \delta_e = (3.22 \pm 0.29) \times 10^{-3} \]

superweak theory : \[ \delta = (2.80 \pm 0.08) \times 10^{-3} \]

The superweak prediction holds for both charge asymmetries if the \( \Delta S = \Delta Q \) rule is valid. From the \( K^0 \) charge asymmetry measurements and a measurement\(^7\) which yielded \( F_e = (0.96 \pm 0.05) \) we obtain:

\[ F_\mu = (\delta_\mu/\delta_e) F_e = 1.79 \pm 0.46. \]

If we assume that \( \text{Im}(x_\mu) = 0 \), as is consistent with the previous measurements\(^8\) of \( x_\mu \) and as is implied by \( T \) invariance in the muonic decay interaction, we obtain \( \text{Re}(x_\mu) = 0.27 \pm 0.12 \).
II. EXPERIMENTAL METHOD

A. Beam

The experiment was located at the end of the second channel of the external proton beam at the Lawrence Berkeley Laboratory's Bevatron. About $6 \times 10^{11}$ protons per Bevatron pulse were received on a 12.7 cm copper target. The neutral beam (see Fig. 1) was defined by a series of tapered collimators to have a solid angle of approximately 0.2 millisteradians about the production angle of 7°.

Charged particles were swept from the neutral beam by four sweeping magnets (Fig. 1). The first magnet was situated between the target and the first collimator.

B. Counters

The detection apparatus consisted of 154 scintillation counters monitored by a DEC PDP-9 computer. The important counter banks are labeled in Fig. 2. $K^0_L$ decays were identified by an up-down coincidence of the large trigger counters labeled $P$ situated outside the neutral beam. The $K^0_{\mu 3}$ component of these decays was identified by separating muons from other particles by requiring penetration of a 61 cm thick lead wall. Muons were required to traverse the lead wall and count in banks L and M. In addition, the muons traversed 5 cm of steel just downstream of the T counters and 5 cm of steel between banks L and M. Those muons reaching the N bank, not required for a $K^0_{\mu 3}$ signature, traversed a third 5 cm steel plate. The system was up-down symmetric. The muon could be up with the pion down or vice versa.

The system was designed to accept $K^0_{\mu 3}$ decays which had a vertex in the decay volume, produced a muon with sufficient momentum to
penetrate the lead wall, but yet also produced both a muon and a pion with sufficient transverse momentum to get out of the beam (i.e. cross over the beamside edge of the appropriate P counter). In order to accept these muons the counter banks increased in size from the upstream end of the experiment to the downstream end (see Fig. 2). The expected muon track would contain P, S, R, T, L, M and perhaps N counts. The pion could indicate its presence by a lone P count or, if it stayed close to the beam, it might produce counts further downstream.

The charge-resolving magnet (M5) had circular pole faces with a diameter of 160 cm and a gap of 132 cm. The field pointed up or down. The M5 imparted a transverse momentum of about 500 MeV/c to particles passing through it. Since the maximum transverse momentum of a muon in $K^0_{\mu3}$ decay is 216 MeV/c, negatively charged muons were given a complete angular separation from positively charged muons. One method of muon charge determination was to observe whether the position of the muon at the L hodoscope was east or west of the center line. In the absence of multiple scattering in the lead wall this method of charge determination would have been completely unambiguous. The charge was also determined by measuring the direction of the muon curvature in the M5. This determination was accomplished using the S, R and T hodoscopes. The method used to bin the muon position in the S, R and T banks is depicted in Fig. 3. For the purpose of binning, the L, M and N banks formed one logical bank called W, also shown in Fig. 3.

The ratio of high energy neutrons to long-lived $K$ mesons in the neutral beam was large, about two hundred to one. Figure 4 shows the rough neutron and $K^0_L$ momentum spectra at the Bevatron. In order to
avoid contamination of the K sample by neutron interactions, all mass was removed from the neutral beam in the decay volume. The geometrical details are illustrated in Fig. 5. The vertical beam profile is indicated showing both the umbra and the large penumbra which was a result of the necessity of collimating close to the target. The anti counter (A in Fig. 2) was actually a set of six counters which acted as a shield against charged particles coming from upstream. It was logically equivalent to a single large counter with a hole in it slightly bigger than the beam. The vertical separation of the upper and lower portions is indicated on Fig. 5 along with the positions of the P counters. An event was accepted only if counts were observed in both P counters but not in the anti counter. Thus, an event originating at a vertex must have originated downstream of the intersection of the two lines $L_1$ and $L_2$ defined by the edges of the A and P counters. In this manner, the decay volume was defined without putting any mass into the beam.

The entire decay volume was kept at vacuum (typically $10^{-5}$ atmospheres). The A, P, and C counters were inside the vacuum tank, and the beam passed into the vacuum through a thin window (0.025 cm aluminum) just downstream of the last sweeping magnet. In order to keep neutron interactions as far as possible from the P counters the beam was brought out of the vacuum tank into a vacuum snout which extended well into the M5 (Fig. 2).

The $S_V$ and $R_V$ counters shown on Fig. 2 provided vertical resolution. Their geometry is shown in Fig. 6a. For events in which the pion reached the R bank, these counters were used in conjunction with the S and R counters to reconstruct the decay vertices.
Figure 7 shows the vertex distribution. Due to randoms and scattering in the vacuum tank wall on the pion side, the long tail extending upstream is expected, and because of pion interactions, the events in the tail are expected to have a charge asymmetry. However, the events upstream of -300 in. only change the charge asymmetry of the whole sample by $3 \times 10^{-4}$. Hence the vertex distribution supports the contention that the upstream acceptance is well understood.

There were two known flaws in the trigger system. First, neutrons in the halo around the beam could have interacted in the anti counter itself. If charged particles were produced by such a neutron interaction sufficiently close to the downstream anti counter edge, the particles would not have registered in the counter. Hence, such a neutron-induced event would have been accepted by the A-P system if these charged particles also counted in both P's.

The second source of error in the above trigger system is that it does not take into account neutron backscatter. Specifically, halo neutrons could have interacted in the walls of the vacuum snout and sprayed low energy particles backward into both P counters. In order to measure the number and charge asymmetry of such events, the horizontal walls of the snout were lined with counters. Counters also were placed below $P_{up}$ and above $P_{down}$ to detect interactions in the P's themselves. The geometry of these guard counters (labeled C) is presented in Fig. 6b. Note that for a neutron interaction to have backscattered from the snout into both P's, both an upper C and a lower C must have counted. This was true even if the interaction occurred in a C counter.
A hole was made in the lead wall to allow the neutral beam to pass through. Unfortunately, this hole also opened a path by which pions could penetrate the lead wall. In order to eliminate these pions, the hole was lined with a steel beam conduit with walls 7.5 cm thick on the sides and 10 cm thick on top and bottom. The conduit was lined in turn with counters (labeled H, Fig. 6b) to detect particles passing through the conduit.

C. Electronics

Because the electronics system has been described elsewhere, only an abbreviated description will be presented here. An on-line, interactive, counter control system was designed and built using a Digital Equipment Corp. PDP-9 computer, a Tektronix 614 CRT, and unique data-acquisition electronics. The system was capable of asynchronous and programmable electronic verification of the discriminator and coincidence circuits for each counter.

After threshold discrimination by a specially designed LBL discriminator, a typical photomultiplier anode signal produced three outputs. One output was used in the formation of a pulse called the prompt strobe which signified that the event under consideration had passed the acceptance criteria on the counter banks upstream of the lead wall. Counter information was stored only when such a strobe was generated. A second pulse for each counter was sent into a coincidence circuit versus the prompt strobe. The resulting bit of information, whether or not the counter in question was on in time-correlation with the prompt strobe, was stored for that counter. A delayed strobe pulse was also generated precisely one Bevatron revolution (403 nsec) after the prompt strobe. This delayed strobe inquired if each counter was on in random time correlation with the prompt strobe. The reason for waiting one Bevatron revolution was to
insure that both time slots sampled the same beam structure.

The LBL discriminators, used primarily because of their low cost, had one serious drawback, a deadtime of about 20 nsec after any output pulse. In order to overcome this deadtime, the coincidence circuit resolving time was increased, so that if the pulse from a genuine event were "lost" due to deadtime, the coincidence circuit would respond instead to the spurious pulse which had produced the deadtime. The coincidence resolving time under these conditions was very long (60 nsec), about three times longer than would otherwise have been required.

The C, H, A, and P counters were not attached to LBL discriminators, but instead to commercial Chronetics discriminators run in a deadtimeless mode; subsequent to discrimination, their respective logical bits were treated electronically the same as the other counters.

Only the A, P, and S counters were involved in the strobe logic, generated by a set of Chronetics coincidence circuits. One additional criterion was imposed before an event was recorded by the computer. Using a matrix of coincidence circuits, the L and M counter bits were electronically analyzed, and the event was accepted only if there was a prompt time (or delayed time) coincidence between at least one L and one M counter. The event was then read out to the PDP-9 computer, to be recorded on magnetic tape at the end of the Bevatron pulse cycle.

Let

\[ \bar{A} \] = lack of an A count
\[ \bar{P} \] = P counter delayed 403 nsec
\[ U, D \] = up, down
\[ P_U P_D \] = coincidence between \( P_U \) and \( P_D \)
\[ S_D \] = OR of 13 S-down counters.
Then if
\[ V_D \equiv \overline{A}P_U P_D \quad \text{OR} \quad \overline{A}P_U P_D \]
and
\[ V_U \equiv \overline{A}P_U P_D \quad \text{OR} \quad \overline{A}P_D P_U , \]
the prompt strobe was:
\[ \text{PROMPT STROBE} \equiv \overline{A}V_D S_D \quad \text{OR} \quad \overline{A}V_U S_U . \]
Thus the system was triggered not only on prompt events but also on the two random configurations which were most important: a muon track with a random pion \( P \) count (delayed \( P \) event) and an \( \overline{A}V_S \) with a random LM signal (delayed \( W \) event).

The system also contained six analog-to-digital converters, which were used to do pulse-area analysis (PAA) and time-to-pulse-height analysis (TPH) of the various counters.
III. DATA ANALYSIS

A. General Analysis

The data from the experiment are stored on approximately 200 reels of magnetic tape; the analysis was done on the Lawrence Berkeley Laboratory's CDC 6600B computer.

Approximately 24 million events were recorded on tape during the data-taking phase of the experiment. About 9 million of these events satisfied a $K^{0}_{\mu 3}$ signature criterion. Most of the unacceptable triggers which failed the signature tests were random triggers. The dominant type was of the kind in which the R and T banks (not required in the trigger) were missing.

The $K^{0}_{\mu 3}$ signature required in the analysis was much more restrictive than the electronic trigger requirement. The signature requirements for prompt and delayed P events were as follows:

- Prompt: $\bar{A}P_D P_S U R U T U W U$ or $\bar{A}P_D D S_D R_D T_D W_D$
- Delayed P: $\bar{A}P_D U S_R U T U W U$ or $\bar{A}P_D D S_D R_D T_D W_D$

Here $\bar{A}$ signifies a bit which was sent to the computer indicating whether or not the anti counter was on. A bit was also sent to the computer indicating whether the information was associated with a prompt or delayed P count.

For a delayed W event, the OR of prompt and delayed bits was formed for each counter before performing the same signature test as carried out on prompt events. If a delayed T count was associated with a delayed W, this information was preserved.

The analysis was performed in two stages. The first pass analysis program calculated and binned for each event the following four quantities
characterizing horizontal projection of the muon trajectory: decay angle, projected position at the anti, bend angle in the M5, and scattering angle in the lead wall. The position of a muon at a given bank was taken to be the center of its bin in that bank.

The second-pass analysis program then made cuts on each of these four quantities. Events which did not possess a muon trajectory with acceptable values of all four of them were excluded from further analysis. The first-pass analysis and a Monte Carlo calculation were used to determine the points at which to make the cuts. Figures 8 through 11 show the points at which the cuts were made. The cuts appear to be quite liberal, as they must be: the result of the experiment is insensitive to the positions of the cuts. After the neutron cut (also discussed below) the second-pass cuts only changed the charge asymmetry by -0.15%.

B. Monte Carlo Program

The Monte Carlo program for this experiment was written in order to perform several important calculations and in general to test and enhance our understanding of the experiment. Approximately five thousand $K^0_{\mu 3}$ events were generated in the K meson rest frame in accordance with the V-A theory as given by Okun'. The $K^0_L$ mesons were given a momentum distribution in accordance with a recent measurement at the Bevatron, done at a $K^0_L$ production angle of 3.7°. This spectrum was extrapolated to our production angle of 7° using a well known prescription. Multiple scattering was calculated in the Gaussian approximation. Energy loss was computed using a linear approximation to the muon energy loss tables. Energy-loss straggling
was calculated according to the theory of Symon as given by Rossi. 13

In Figs. 8-11 the Monte Carlo predictions for various distributions are compared with the data. Statistical error bars are shown if they are bigger than the corresponding points. Agreement is good between the predicted and actual distributions in all cases. (The slight broadening of the actual peaks in the bend-angle and scattering-angle distributions is thought to be due to 1-bin-shift knock-ons, to be discussed below.) The Monte Carlo predictions are shown in Fig. 12 for the muon and pion momentum spectra occurring in accepted events.

C. Mass Extrapolations

Three effects (pion absorption in the P counters, neutron interactions in the anti counter, and neutron interactions in the residual air in the decay volume) are treated through the use of linear mass extrapolations. The procedure is to add mass in various regions of the apparatus in order to extrapolate the charge asymmetry to the result which would be obtained by an ideal zero-mass detector. In all extrapolations the added material was identical to that used in the detector. The zero-mass intercept was found by doing a minimum $\chi^2$ fit of the measured points to a straight line.
IV. CORRECTIONS

A. Introduction

Table VII contains a summary of all of the various corrections. Two of the most important are due to the "neutron cut" (described in detail below, in which certain high momentum trajectories are excluded) and the presence of knock-on electrons, which produce ambiguous events. Each of these two has been assigned a systematic error of $\pm 5 \times 10^{-4}$. The range difference between $\mu^+$ and $\mu^-$ is responsible for a third large correction with a systematic error of $\pm 7 \times 10^{-4}$. The correction for the dilution of the charge asymmetry due to pion decay in flight has a similar systematic error when listed as an additive correction.

A correction to the charge asymmetry was considered negligible if it was less than $10^{-4}$ in magnitude and error (one standard deviation). The term "good events" will be defined below. These events made up the relatively uncontaminated portion of the data remaining after a cut had been employed to free the data of neutron interactions. The term "uncorrected good events" refers to these events after the neutron cut had been made but before any other corrections had been applied (including the knock-on correction which was associated with the neutron cut).

In all histograms, event lists, and calculations, the delayed W and delayed P random-trigger events have been subtracted (bin by bin where applicable) unless otherwise noted.

B. Reversal of the Magnetic Field

Frequent reversal of the charge-resolving magnetic field is the cornerstone of the experimental technique required to do this experiment. We define:

- $N = \text{total number of } K^0_L \text{ which decayed to } \pi\mu\nu \text{ downstream of our last collimator during the experiment.}$
- $\eta_{R, L} = \text{efficiency for detecting these } K^0_{\mu L} \text{ events if the muon bent right (or left)}$
- $N_{\pm} = \text{number of } K^0_{\mu L} \text{ in } N \text{ having a } \mu^\pm.$
- $n_{\pm} = \text{number of } K^0_{\mu L} \text{ detected having a } \mu^\pm.$

The true charge asymmetry in $K^0_{\mu L}$ decays (within the statistical error on $N$) is
We define the efficiency asymmetry to be:

\[ a = \frac{\eta_R - \eta_L}{\eta_R + \eta_L}. \]

If "↑" and "↓" denote events taken with the field up and down respectively, then we have \( N↑ + N↓ = N \), and

\[ \delta = \frac{N↑ - N↓}{N↑ + N↓} \]

The geometric bias is defined to be

\[ \Lambda = \frac{1}{2} \left[ \frac{n↑ - n↓}{n↑ + n↓} \right] = \frac{1}{2} \left[ \frac{\delta + a}{1 + a} \delta - \frac{\delta - a}{1 - a} \right] \]

where we have included the possibility that the efficiencies might depend on the sign of the magnetic field. In this experiment, the \( \delta \)'s and a's all are \(< 10^{-2} \). So to an accuracy of \( 10^{-4} \) of \( \Lambda \):

\[ \Lambda = \frac{\delta↑ - \delta↓}{2} + \frac{a↑ + a↓}{2} = \frac{a↑ + a↓}{2} = a. \]

The geometric bias is equal to the average asymmetry of the efficiencies.

The expression which was used to define the measured charge asymmetry is as follows:

\[ \delta_{\text{measured}} = \frac{n↑ - n↓ + n↑ - n↓}{n↑ + n↓ + n↑ + n↓}. \]
To an accuracy of $10^{-4}$ of $\delta_{\text{measured}}$:

$$\delta_{\text{measured}} = \delta + \frac{a^+ - a^-}{2} + \Lambda \alpha,$$

where

$$\alpha \equiv \frac{N^+ - N^-}{N^+ + N^-}.$$

Here $\alpha$ is zero if an equal number of events are taken with the field up and down. For this experiment, the last term in $\delta_{\text{measured}}$ is negligible ($1.0 \times 10^{-6}$).

However, from the expression for the measured charge asymmetry it can be seen that it is crucial that the efficiencies must not depend on the sign of the magnetic field; a difference in the efficiency asymmetries with the field up and down enters directly into the measured charge asymmetry. There are two ways that the efficiencies might depend on the sign of the field: via the counting efficiency of the detectors, and via the geometrical efficiency of the volume occupied by the detectors. These two possibilities will be considered in turn.

The reason for reversing the magnetic field frequently is to cancel out the effect of a possible slow, long-term variation of the efficiency asymmetry. The magnetic field was reversed approximately every 10,000 events for a total of about 600 reversals during the data-taking phase of the experiment.

C. Counting Efficiency

A major advantage of having performed this experiment with counters rather than spark chambers is that the counting efficiency was measured very accurately. It can be demonstrated that the efficiency asymmetry did
not change with the magnetic field reversals to an accuracy of one part in $10^{-4}$.

All counters in the A, P, S, R, T, L, M, N, and H banks were tested in an auxiliary beam of 2.8 GeV/c before their use in the main experiment. Each counter had its high voltage set at a level such that the inefficiency at the worst spot on the counter was less than $10^{-4}$ with the output pulse attenuated by a safety factor of 2 (factor of 1.25 for the W counters). During the data-taking phase of the experiment the counter pulse heights were periodically monitored with an oscilloscope. The pulse height of any counter required in the $K^0_{\mu 3}$ signature was never observed to have sunk so low that its inefficiency became greater than $10^{-4}$, considering the above safety factors.

Pulse area analyses were also performed for every counter (except the antis) required in the $K^0_{\mu 3}$ signature using muons from the prompt events. The peak position never shifted beyond the PAA measurement error of $\pm 7\%$ with the reversal of the magnetic field, which is another confirmation that the efficiency of each counter was constant under field reversal, to one part in $10^{-4}$. This implies that the efficiency asymmetry was also constant to one part in $10^{-4}$. All counting rates were also checked approximately every four hours while taking data, and no counter required in the $K^0_{\mu 3}$ signature ever failed.

D. Geometrical Efficiency

One way that the geometrical efficiency of the counters could have changed with field reversal is that the field may have indeed not reversed completely. Suppose that under reversal, the field actually changed from (-B) to (+B + \Delta B). In this case, more muons would have been bent outside the region subtended by the T bank, resulting in a
loss of efficiency with the field up. This effect alone would still not have caused a change in the measured charge asymmetry since \( \eta_R \) and \( \eta_L \) would have changed by equal amounts. Only a change in the efficiency asymmetry would have affected our measurement. However, such an irreversal of the field could have combined with misalignments or the horizontal asymmetry of the beam to produce a change in the efficiency asymmetry. The experiment was designed in such a way that the major \( K^0_{\mu 3} \) acceptance cuts were made before the magnetic field, so that the efficiency asymmetry would be insensitive to field irreversal. The field was monitored by three coils which were flipped pneumatically approximately once every four hours. Using these coils, it was determined that the total field integral reversed to an accuracy of \( 2 \times 10^{-3} \).

In order to study the effects of a possible non-reversal of the total field integral a series of runs was taken with the magnet current set 2\% below its normal value. For a 2\% decrease in the current, the measured change in the efficiency asymmetry was \( \Delta a = (-2.4 \pm 3.0) \times 10^{-3} \). As the field is known to reverse to at least \( \pm 2 \times 10^{-3} \), the maximum effect on the charge asymmetry was:

\[
\Delta \delta_{\text{measured}} = \frac{\Delta a}{2} = (-1.2 \pm 1.5) \times 10^{-4}.
\]

However, because any possible field irreversal was probably due to the accuracy with which the current could be set, and was therefore random, no correction will be made.

E. Charge Determination

Neither method of charge determination used in this experiment was without fault. The L counters could provide the wrong sign for
a small fraction of the muons, due to multiple Coulomb scattering in the lead wall. The sign could also be ambiguous if the W bin criteria were satisfied on both west and east sides of the L bank. The S-R-T determination was often ambiguous if an extra S, R, or T counter were on, or if the track under consideration had high enough momentum that it looked essentially straight in the apparatus. The term "track" will be used to describe a combination of S, R, T, and W bins which represents a trajectory. If an event had more than one muon track, the S-R-T charge determination was unambiguous only if all tracks had the same sign of curvature. Table I shows the number of events possessing each possible type of charge determination. The results are presented for the data sample labelled "good-NCC" (defined below) which will be used to calculate the $K_{\mu 3}^0$ charge asymmetry.

The charge resolution is quite good. As a fraction of the total number of events:

- $4 \times 10^{-4}$ fail S-R-T determination
- $4 \times 10^{-4}$ fail L determination
- $3 \times 10^{-5}$ fail both
- $3 \times 10^{-3}$ have disagreement between the two methods.

The S-R-T method is chosen to determine the muon charge when possible. Where the S-R-T method fails, the L method is used. If the failure in the S-R-T method is uncorrelated with a wrong decision in the L method, then the wrong charge is chosen for only $1 \times 10^{-6}$ of the events.

The reason that the charge resolution is so good for the above sample is that many of the problems have been excluded in the bend angle (neutron) cut to be discussed below. The S-R-T method fails mainly for events with a
small bend angle for two reasons: it cannot resolve a straight track, and an event with two tracks of opposite charges is likely to have one track with a small bend angle (where the charge of the trajectory changes). As explained below, the track with the smallest bend angle is chosen to represent a multiple track event.

In the above data sample, the double penetration events which possess muon tracks both up and down have been omitted. For these events, comprising $(0.22\pm0.01)\%$ of the data, the muon cannot be identified. A Monte Carlo calculation predicts that $(0.21\pm0.03)\%$ of the data are double penetration events due to pion decay in flight from $K^0_{\mu3}$. Hence it is believed that these events are understood.

F. Neutron Interactions

Figure 4 shows the neutron and $K^0_L$ momentum spectra. The neutron spectrum is peaked at very high momentum and thus unfortunately can produce very high momentum secondaries. One type of neutron interaction which could have been accepted involves low energy spray to trigger the P counters and a fast hadron with very high momentum to penetrate the lead wall. Another type of neutron interaction (not requiring that a hadron penetrate the wall) would involve decay in flight of a fast pion.
Some data were taken with the anti requirement removed from the trigger. It was found that for events satisfying a $K_\mu^0$ signature requirement (with the exception of the anti requirement), the ratio of the number of events with anti-on to anti-off was (1.1). The charge asymmetry of the events with the anti on was $(0.4\pm0.9)\%$. Thus the maximum contribution to the measured charge asymmetry due to anti inefficiency is $4\times10^{-7}$ using an inefficiency of $10^{-4}$. Hence we believe that the anti counter was effective and therefore neutron interactions could have triggered our system from only two places: the snout area and the anti itself. These two possibilities will be discussed separately below.

1. Neutron Cut

There were two means of detecting neutron interactions in the snout (Fig. 6b): the C counter up-down coincidence, and the $S_{V_1}$ counter labeled $S_{V_1'}$, nearest the beam on the muon side. Neither means could be used as an absolute veto to exclude neutron events. The $S_{V_1}$ detected the events coming from the most likely area of origin, the upstream portion of the snout and the vacuum tank wall near the beam. The C counter coincidence could not be used as an absolute veto mainly because pions from $K_\mu^0$ might have interacted asymmetrically in the snout before triggering the coincidence.

Because there was no absolute neutron veto, the philosophy was adopted of studying the data in the hope that a portion of it was free of neutrons and hence insensitive to the state of the C coincidence and $S_{V_1}$. In order to aid in this study, the following abbreviations will be adopted:
ALL = all events (surviving second-pass cuts)
CC = events with C coincidence on
NCC = ALL events excluding CC events
CCSV = events with C coincidence and SV on
NCCSV = ALL events excluding CCSV events

In the following discussion a series of plots will be presented containing as the abcissa the magnitude of the tangent of the muon bend angle in the M5 magnet. This quantity will generally be referred to simply as the "bend angle". The bin size used for the bend angle is 0.06. From the geometry of the counters, the calculated bend angle resolution is ± 0.12. Thus it is possible for an event to appear as much as two bend-angle bins from its true location.

To see the effect of the C-counter coincidence on the data, Fig. 13 shows the distributions of the number of events and charge asymmetry vs. bend angle for the NCC and CC single-track events. Neutron contamination is evident. There is a very large charge asymmetry in the high momentum bins, where very few muons from $K^0_{\mu 3}$ are expected. A strong correlation between the charge asymmetric events and the C coincidence is seen, indicating that many of these events originated in the snout downstream of the vacuum tank. The large charge asymmetry in the high-momentum NCC events is mainly due to neutron interactions in the anti counter. Apparently, whether the event was made in the anti or the snout the culprit was the same: the type of neutron interaction is which a hadron penetrated the lead wall. These events appear to have left relatively uncontaminated much of the region where the real muons are expected (bins 0.24 to 0.48) as in Fig. 11.
The low momentum events also show a charge asymmetry which is correlated with the C coincidence. The nature of these events is somewhat puzzling because the minimum muon momentum penetrating to the M bank is 1075 MeV/c (bend angle bin 0.48). One possibility is that they are neutron induced events, where the neutron penetrates the lead wall and converts to form a W bin. The SRT requirement could then be satisfied by a pion, associated with the neutron, which does not penetrate the wall but happens to point to the neutron's W. In that case one would be measuring the charge of the pion. These events will be included in the good event sample and the uncertainties associated with them will be incorporated into the systematic error of the neutron cut. However, these events represent no problem. There are so few of them that the effect on the charge asymmetry is less than $10^{-4}$.

Figure 14 is an expanded view of the charge asymmetries under the muon peak. There are systematic differences between the NC and CC events throughout the plot. In bins 0.24 and 0.54 the differences are apparently due to the high and low momentum background events just discussed. In bins 0.36 and 0.42, however, the CC events have a negative charge asymmetry. There are two likely causes for this asymmetry: neutron interactions where the particle penetrating the lead wall is a muon from pion decay in flight; or asymmetric interactions of pions from $K_\mu^0$ before triggering the C coincidence. The first type of event should not be included in the charge asymmetry measurement while the second type should. Hence, the net effect of these events on the charge asymmetry represents a systematic error. The most likely explanation is that these events are produced by neutrons since the neutron interactions
in the anti counter have a negative charge asymmetry in this region (as discussed below).

The size of the systematic error introduced by neutron interactions is studied in Fig. 15. Here the asymmetries of the NCC, ALL, and NCCSV events are plotted in order to study the effect of the CC events on the charge asymmetry of each bin. The statistical errors of the NCC points have been indicated. With the sole exception of bin 0.24, the difference between the ALL and NCC asymmetries is about equal to or less than the NCC statistical error. The NCCSV curve, however, shows agreement with the NCC curve for all bins including bin 0.24. Hence the discrepancy in bin 0.24 is due entirely to CCSV events, which have been labeled as neutron candidates by both means of identification. If the CCSV events from bin 0.24 are excluded, apparently the systematic error in excluding neutrons can be reduced to about the same size as the overall statistical error. Thus we define the term "Good Event":

Good Events = NCCSV events with bend angle bin ≥ 0.24 + CCSV events with bend angle bin ≥ 0.30.

There are 4380674 good, single-track events in the main data sample. The exclusion of all events with bend angle bin ≤ 0.18, and CCSV events in bin 0.24 will be termed the "neutron cut."

Using Fig. 16, the neutron cut can be examined from an integral point of view. Here the NCC, NCCSV, and ALL charge asymmetries have been plotted for all bend angles greater than or equal to a given value. For the total sample, the CCSV events have a large effect on the charge asymmetry (about 0.6%). However, after bin 0.18 has been cut away, this effect has been reduced to about 0.1% (two NCC standard deviations). The effect then remains at about one NCC standard deviation across the muon peak.
The neutron cut includes 92% of the single-track data in the good event sample. Note that the charge asymmetry of good-NCC single-track events (bend angle bin $\geq 0.24$) differs from the good event single-track charge asymmetry by only $2 \times 10^{-4}$.

$$\delta \text{(good ALL, single-track)} = (-2.2 \pm 4.8) \times 10^{-4};$$
$$\delta \text{(good-NCC, single-track)} = (-0.1 \pm 5.1) \times 10^{-4}.$$

The independence of the charge asymmetry from the state of the C coincidence (as is apparent from these numbers and from Fig. 16) is the reason for believing that the "neutron cut" does indeed exclude the effects of neutrons. The strong correlation between neutron-induced events and the state of the C coincidence is proved by the high momentum bins of Fig. 16. The effectiveness of the neutron cut is obviously due to the fact that most of the neutron interactions which trigger the system are associated with hadrons penetrating the lead wall; such penetration apparently requires a much higher momentum than is required for a muon penetration.

"Multiple-track events" are those with more than one track on the muon side of the apparatus. In most cases, these events had only one extra bin firing in one of the S, R, T, or W banks with only one bin firing in the other three, producing an ambiguity. Multiple-track events constitute 10.8% of the data which pass the second pass cuts. Because of the need for a neutron cut, these events are a serious problem. If such an event has an extra S, R, or T counter on, there is an ambiguity in its assignment to a bend angle bin. In order to be sure to exclude the high momentum neutron-induced events, when such an ambiguity arises, the track with the smallest bend angle is chosen to represent the event. This procedure, though necessary, causes serious problems in the analysis of events with knock-on electrons.

Consider a $\mu^-$ which makes a knock-on in the R counters. The electron will spiral around in the magnetic field and, if it has sufficient
energy, it may count in an R bin separate from that of the muon. Since
the knock-on has the same charge as the \( \mu^- \), it will always spiral in the
same direction as the \( \mu^- \) bends. Hence, the track including the knock-
on R count will always have a higher momentum than the real \( \mu^- \) track
(unless the knock-on travels so far that its track has the curvature of
a \( \mu^+ \)). By the same reasoning, a \( \mu^+ \) can only produce a knock-on track
of lower momentum. Hence, due to the above analysis procedure,
knock-ons will shift \( \mu^- \) tracks to smaller bend angles but will leave \( \mu^+ \)
tracks in their proper bins. Then the neutron cut, when applied to
multiple track events, will preferentially exclude \( \mu^- \).

Aside from the large effects of knock-ons, the multiple-track data
are qualitatively the same as the single-track data. Figure 17 pre-
sents the integral curves for all events (single and multiple track) and
corresponds to Fig. 16. The uncorrected charge asymmetries for
good events and good-NCC events are as follows:

\[
\delta_{\text{good}} = (5.03 \pm 0.46) \times 10^{-3};
\]

\[
\delta_{\text{good-NCC}} = (5.16 \pm 0.49) \times 10^{-3}.
\]

The two numbers are essentially identical. The second one is the best
value for the charge asymmetry before other corrections. The above
errors are statistical only. In accord with the previous discussion an
additional systematic error of \( 5.0 \times 10^{-4} \) (equal to the statistical error)
is applied to take into account the inability to exclude the effects of
neutrons.

About 4.4% of the events are multiple-track due to randoms. From
the analysis to be described below it is shown that an additional 4.7%
are multiple-track from knock-on events. Thus these two sources account for most (and perhaps all) of the 10.8% of the data with multiple tracks. Since it has been shown that the good events and the good-NCC events are equivalent, only the good-NCC events will be considered in the discussion of the remaining corrections.

2. Residual Air in the Decay Volume

In order to perform the residual air mass extrapolation, a small amount of data was taken with the vacuum tank at atmospheric pressure. A total of 3180 events was accumulated with bend angle bin $\geq 0.24$, with a charge asymmetry of -3.5%. As the ratio of mass added to initial mass was about $10^5$, the correction is negligible.

3. Anti-Mass Extrapolation

Figure 18 shows the charge asymmetry as a function of anti counter effective thickness. The high-mass points of this plot were taken with scintillator placed just downstream of each of the six separate anti counters, so as to increase the inactive volume of each counter in which neutrons could generate background events. The fractional inactive length of each counter was taken to be the ratio of the electronic discrimination level to minimum-ionizing pulse height. However, more than one charged particle must have been created by any relevant neutron interaction, in order to trigger the P's. Since neutron interactions often have high multiplicity, and the secondaries may have high ionization losses, the average multiplicity is taken to be $3^{+3}_{-1}$. The inactive length is divided by the multiplicity to obtain the effective inactive length, which is the low mass value of Fig. 18. The assumed error in the multiplicity then corresponds to an error of $\pm 0.11 \text{ g/cm}^2$ in the placement of the origin of the mass axis.
The confidence level for the straight line fit is only 3% but the correction is small, only $(3.8 \pm 1.2) \times 10^{-4}$. An additional error of $1.2 \times 10^{-4}$ is assigned as a result of the uncertainty in the average multiplicity. Hence, the anti-mass correction to the charge asymmetry is:

$$\Delta \delta = (3.8 \pm 1.7) \times 10^{-4}.$$  

Figure 18 also shows the charge asymmetry per bend-angle bin from 0.24 through 0.54 as a function of anti-mass. This plot is useful because it shows the effect of a known source of neutron interactions in these bins. The plot substantiates the claim that the NCC events in these bins are free of neutrons, but that the CC events are not.

G. Knock-On Correction

Figure 19 illustrates the different ways in which a knock-on electron can affect an event. The 2-bin knock-ons are the type in which the electron merely causes a second bin to be on. However, due to the idiosyncrasies of the binning scheme, a knock-on can cause three bins to be on, or can shift the apparent muon position with or without the turning on of a second bin. A 3-bin knock-on can occur only if the real muon bin has two counters on; a shift of the muon position can occur only if the real muon bin has only one counter on.

The knock-on correction was studied both from the data and from the Monte Carlo events. Knock-ons were generated by the Monte Carlo according to the energy distribution given by Rossi. The kinematic maximum knock-on energy was calculated separately for each muon. The minimum knock-on energy was taken to be 1 MeV. Fortunately, the magnetic field was so strong (6 000 G) that the calculation is very insensitive to this lower limit, which is not well known. Only 0.14% of the knock-ons which affected the muon track were less than 2 MeV.
The most important knock-on effect occurs in the R-bank, located near the middle of the magnet. Consider all NCC multiple-track events containing just two tracks, with different R bins only. (Include the 3-bin configuration in Fig. 19). This sub-sample represents 2.0% of the NCC data, and its net charge asymmetry before the neutron cut is very small, only (1.1±0.3)%. Thus in the absence of the neutron cut the charge asymmetry is similar to that of the total data. However, if the correlations between the two tracks are examined, it turns out that there are very large knock-on-type correlations. Thus, consider events in which one track is in bend-angle bin 0.30 and the second track is 3 bins displaced. If the second is in bin 0.48 the experimentally measured charge asymmetry is +45%, but if the second track is in bin 0.12, the measured charge asymmetry is -49%. This indicates that perhaps 45 to 50% of these events are knock-ons. Because the neutron cut is made in bin 0.24 and as the criterion used was to choose the straightest track for all multiple-track events, a correction must be applied to account for the events which knock-ons place asymmetrically in the neutron cut. The approach taken is to assume that the entire charge asymmetry, in the bin under consideration (45±2% in the above example) was due to knock-ons, and simply to add back the required number of events of the proper sign. The resulting corrections are shown in Table II for each bend angle bin.

Similar studies were made for the Monte Carlo knock-on events, and the resulting predictions are also presented in Table II. The statistical errors of the Monte Carlo predictions are negligible compared to the systematic error of about 10%. The measured corrections have no statistical error since they are direct measurements of the events.
concerned, if the above assumption of zero charge asymmetry in each bin except for knock-ons is justified. The agreement between Monte Carlo and measured corrections for bend angles $\geq 0.36$ is excellent, and instills confidence in the Monte Carlo. However, the agreement near the neutron cut is poor and this disagreement will be the basis for the estimate of systematic error.

The 1-bin-shift knock-ons (Fig. 19) are especially troublesome since they do not indicate their presence with an extra track. They are believed to be responsible for the increase of the NCC single-track charge asymmetry as a function of bend angle (Fig. 15). They occur only when the muon goes through a single-counter (odd-numbered) $R$ bin as shown in Fig. 19. Since they produce single-track events, they shift positive muons toward larger bend angles but negative muons toward smaller bend angles. A positive charge asymmetry of the even-numbered $R$ bins in good-NCC events is caused by the shift of positive muons to an even bin, while the corresponding negative muon is lost in the neutron cut. Hence, by studying the events in the neutron cut the number of these lost negative muons can be measured. Assuming that the neutron-induced charge asymmetry does not depend upon whether the apparent muon goes through an odd or even $R$ bin, the measured 1-bin-shift knock-on correction in Table II is the difference of the asymmetric events with odd and even $R$ bins in the neutron cut. The corresponding Monte Carlo correction is also listed.

The total $R$ knock-on corrections to the charge asymmetry from the data and Monte Carlo are also given in Table II. The final $R$ knock-on
correction to the good-NCC events is taken to be the average of the two
corrections. The systematic error is taken to be about half their difference.
\[ \Delta \delta_{R \text{ knock-on}} = -(5.09 \pm 0.50) \times 10^{-3} \]

This correction is independent of the state of the C-coincidence. The
corresponding correction for good events is
\[ \Delta \delta_{R \text{ knock-on (good)}} = -(5.01 \pm 0.50) \times 10^{-3} \]

The corrections for knock-ons in the S and T banks are much
smaller than the R correction because the magnetic field was weak
enough near the S and T banks that most of the appropriate knock-ons
were stopped by 1.2 cm of wood, just downstream of these banks. These
corrections are opposite in sign to the R correction. The measured
corrections are:
\[ \Delta \delta_{S \text{ 1-bin-shift}} = +(1.7 \pm 0.4) \times 10^{-4} \]
\[ \Delta \delta_{T \text{ 1-bin-shift}} = +(2.4 \pm 0.4) \times 10^{-4} \]
\[ \Delta \delta_{S \text{ Multiple-track}} = +(1.4 \pm 0.4) \times 10^{-4} \]
\[ \Delta \delta_{T \text{ Multiple-tank}} < 10^{-4} \]

The correction for all knock-ons is then:
\[ \Delta \delta_{\text{all knock-ons}} = -(4.54 \pm 0.51) \times 10^{-3} \]
This correction restores the charge asymmetry nearly to its single-track value as might be expected.

We note here that the effects of extra tracks caused by strong interactions of pions before decay are properly accounted for by the use of measured knock-on corrections. Such extra tracks are expected to have a positive charge asymmetry and thus cannot be the cause of the discrepancy between the Monte Carlo and measured corrections for R knock-ons.

H. Randoms

Figure 20 illustrates some of the possible types of random events which might have been accepted. Type 1 represents the real events, and types 2 and 3 represent the random-trigger events which were continuously monitored through the use of delayed-time triggers. Correlated counts are joined by a line representing a particle's trajectory. Uncorrelated counts are not joined. Event type 4 illustrates why randoms
subtractions are notoriously unreliable. This type of event is included in the measurement of all of the first three types. Hence, when one subtracts the measured types 2 and 3 from 1, one subtracts type 4 twice. Events of type 4 cannot be measured by any randoms monitoring technique which uses two time slices. Since three time slices were actually used in this experiment, events of type 4 could be properly measured. However, there is an infinite number of randoms configurations which could not be measured. A randoms subtraction thus makes sense only if the beam intensity is sufficiently low that only a few of the many possibilities need to be considered. Fortunately, this was true for this experiment. The on-times of individual counters (the on-time is defined as the probability that a counter or counter configuration is on at a random point in time) were typically about 0.3%, and for all W bins combined the on-time was about 0.2%.

1. Measured Random Triggers

The randoms subtractions which have been made on the main data sample are listed in Table III. The main problem involved in making the measurements was to ensure that prompt and delayed time slices were equivalent. Because the separation between time slices was precisely the time of one Bevatron revolution, beam structure was properly taken into account. Another consideration was to ensure that prompt and delayed time coincidence circuits had equal resolving times. This equality was established to within ±5% for all relevant circuits. Hence, it is believed that these randoms subtractions were measured to a systematic accuracy of ±5%. Measured random triggers account for only 1.8% of the data, and thus the statistical error of the randoms subtraction is
negligible (1% of δ). The correction for measured random-trigger events is:

$$\Delta \delta = (-12.1 \pm 0.6) \times 10^{-4}.$$ 

2. Unmeasured Randoms

The main problem in making a randoms subtraction is knowing whether one is subtracting all of the necessary events. Since the R and T banks were generally not required in the trigger logic, events of types 5, 6, and 7 (Fig. 20) were correctly subtracted with the delayed W events. However, events of type 8, 11, and 14 would be correctly subtracted only if the S bank was not in the strobe. Such events were studied via the S time-to-pulse-height analyses. The contribution to the charge asymmetry of these random S events is:

$$\Delta \delta_{S} = (0.3 \pm 1.4) \times 10^{-4}.$$ 

Events of types 9 and 10 satisfy requirements for a $K_{\mu 3}^{0}$ signature which are only slightly less stringent than normal. The M counter randoms are charge symmetric, and random P counts must be charge symmetric, because the P counters are upstream of the magnetic field. Hence, events of types 9 and 10 are accepted as $K_{\mu 3}^{0}$.

The contribution to the charge asymmetry of Type 4 events is $2 \times 10^{-5}$. This number was determined by multiplying the delayed P contribution (type 2) by the ratio of the asymmetric muon events of types $PSRT_1 W / PSRT_2 W$. Events with the pion P and muon W correlated in random time, such as event type 13, make a contribution to the charge asymmetry of less than $10^{-4}$.

Hence, the randoms subtraction has performed the necessary correction to the charge asymmetry for random events to an
accuracy of $2 \times 10^{-4}$. The error of the randoms subtraction is increased accordingly.

3. Single-Bin Randoms

The main effect of single-bin randoms is to shift the apparent muon position in a given bank in the same manner as accomplished by knock-ons (see Fig. 19). However, randoms are much less important than knock-ons because they are not correlated with the muon track. For a given bank we define:

$$\Lambda_i = \text{geometrical bias of events in bin } i$$

$$0_{i}^{\uparrow} = \text{on-time probability of bin } i \text{ with the field up.}$$

Then a reasonable definition of the effective charge of a random in bin $i$ is $\Lambda_i$ if the field is up and $-\Lambda_i$ if the field is down. Hence, the on-time for asymmetric randoms in bin $i$ is given by $\Lambda_i (0_{i}^{\uparrow} - 0_{i}^{\downarrow})/2$.

The sum of the asymmetric on-times (average of up and down) is found to be $(65 \pm 3) \times 10^{-4}$ for the T bank, and less than $(2 \pm 3) \times 10^{-4}$ for each of the S, R, L, M, and N banks. As in the case of knock-ons the main danger is that single-bin randoms may shift the bend angle of events asymmetrically into the neutron cut. Less than about 30% of the randoms in an S, R, or T bank are close enough to any particular muon track to affect its bend angle. Hence, the above numbers indicate that the effects of randoms in banks other than the T bank are completely negligible.

Using a method similar to that employed in studying the R knock-on correction, the effects in the T bank change the charge asymmetry by less than $10^{-4}$. 
I. PION INTERACTIONS

1. P Counter Mass Extrapolation

The P mass extrapolation was performed in order to measure the charge asymmetry in the absorption of $K^0_{\mu 3}$ pions before they could traverse the inactive length of a P counter. The plot is shown in Fig. 21. Differing amounts of wrapped scintillator were placed upstream of $P_{\text{up}}$ and $P_{\text{down}}$ to provide the two high-mass points. The two low-mass points represent the portions of the main data with the pion up and down. The two P counters were run with different discrimination levels in order to provide these two points. The straight line fit is good and the correction is $\Delta \delta = (0.9 \pm 3.6) \times 10^{-4}$.

This correction is consistent with the assumption that $\pi^-$ charge exchange on the free hydrogen in scintillator is the only important cause of $\pi^+/\pi^-$ differential absorption in the system. Apparently the system is insensitive to the final state differences of $\pi^+$ and $\pi^-$ charge exchange on carbon. The sensitivity to these final-state differences cannot be calculated reliably, and could be highly dependent on the experimental configuration.

2. Penetration of Lead Wall

This section deals with the possibility that pions penetrated the lead wall without decaying and were thus identified incorrectly as muons. (Decay in flight is considered in the next section.) Since this penetration is a small effect, the main concern is that pions may have penetrated the lead wall asymmetrically.

One possible mechanism for this penetration is the passage of pions through a portion of the hole in the lead wall. Such events must
register an H count. Events with an H counter on comprise 5.3% of the data, of which 3.1% is due to H randoms. The contribution of all H events to the charge asymmetry is \((-2.7 \pm 1.1) \times 10^{-4}\). This contribution is small but not negligible. However, the H counts associated with this contribution are not correlated with the W bins of their events. Hence, this slight charge asymmetry is attributed to interactions of pions from normal \(K_L^0\) events which did not penetrate the lead wall. Consequently, no correction will be made for this effect.

The most direct route for pions to take to the L bank is through the entire lead wall. It is known, from the analysis described above, that some strongly interacting particles (probably high energy protons) are able to take this path. Since the lead wall was only about five interaction lengths thick (including steel plates), probably about 0.7% of such protons passed through the wall without having a strong interaction at all. The pions from \(K_L^0\) decay, however, are expected to have a much smaller penetration probability, due to their lower momenta and higher cross-sections near the first pion-nucleon resonance. One possible way of differentiating these pion penetrations from the main muon sample is to examine events with multiple W-bins, because pions traversing lead at the end of their range can be expected to produce two or more high-energy, spatially-separated tracks much more often than muons.

Calculations indicate that essentially all of the events with multiple W-bins were due to muon knock-ons. Their measured asymmetry was small: in the good-NCC sample, the asymmetric events \((N_+ - N_-)\) numbered \(-476 \pm 365\). Assigning all of these events to asymmetric pion penetration, and assuming that 1/3 of all penetrating pions
were detected through the mechanism of multiple-$W$ bins (as indicated by the measured detection efficiency for protons which were identified by their charge asymmetry\textsuperscript{3}), the maximum correction to the charge asymmetry was $(4\pm3)\times10^{-4}$. However, since the observed asymmetry was small and not statistically significant, no correction will be made for pion penetration.

3. Decay in Flight

A Monte Carlo calculation predicts that $14\pm2\%$ of the events are actually due to pion decay in flight. The mechanism is $K_L^0$ decay to a mode yielding two charged particles into the acceptance; one of these is a pion, which subsequently decays to a muon, which in turn penetrates the lead wall. The calculated contributions from various $K_L^0$ decay modes are shown in Table IV.

The charge asymmetries of the pions in each decay mode are also listed in Table IV. The $K_{e3}^0$ result is taken from Marx.\textsuperscript{5} The asymmetry in $K_{\mu3}^0$ decay is the result of this experiment. These pion charge asymmetries change as the pions interact while traversing the system. The concern here is with penetration mechanisms in which the particle penetrating the lead wall is a muon. The only feasible way in which muons can be produced is from decay-in-flight of $\pi$ and $K$ mesons. Since $\pi^+$ and $\pi^-$ are isospin conjugates, only $\pi^\pm$ interactions with unpaired nucleons can cause an asymmetry in the number of $\pi^\pm$, and thus an asymmetry in $\mu^\pm$ after pion decay. However, this is not true if $K^+$ mesons are produced, because the isospin conjugate of the $K^+$ is the $K^0$, not the $K^-$.  

The main cause of charge asymmetry in pion decay in flight is preferential absorption of one charge over the other. Extensive data exist on the $\pi$-nucleon cross sections.\textsuperscript{17} The absorption cross section $(\sigma_a)$
on a nucleon is taken to be the difference of the total and elastic cross sections. With this definition, it is found that \[ \sigma_a(\pi^- p) - \sigma_a(\pi^+ p) = 5 \pm 2 \text{ mb} \] for incident pions in the momentum range of interest (1.2 to 2.5 GeV/c).

The mass in the path of the pions upstream of the T bank, for most of the data-taking, consisted of 12.0 g/cm² of aluminum and 6.5 g/cm² of wood and scintillator (both taken to be CH). If the contribution to the charge asymmetry is calculated from pion interactions with the hydrogen nuclei, using the above cross section difference, it is found that \[ \Delta \delta = 6 \times 10^{-5} \]. The corresponding calculation for the unpaired neutron in each aluminum nucleus yields \[ \Delta \delta = -5 \times 10^{-5} \]. Pion interactions in the lead wall and steel plate near the T counters produce similarly small changes in the charge asymmetry. \( K^+ \) associated production followed by \( K_{\mu 2}^+ \) decay is completely asymmetric but the relevant \( K^+ \) production cross sections are small. 18 The change in the charge asymmetry is again negligible \( (5 \times 10^{-5}) \). Therefore, the correction for the asymmetric events caused by decay in flight is entirely due to the CP-violating asymmetry in \( K_{\mu 3}^0 \) and \( K_{e 3}^0 \). The correction is \[ \Delta \delta = + (5.7 \pm 1.0) \times 10^{-4} \].

Because decay in flight accounts for a significant fraction of the data, an additional correction must be made after all other corrections to compensate for the dilution of the charge asymmetry by decay in flight.

J. Muon Interactions

1. \( \mu^\pm \) Range Difference

The range difference between \( \mu^+ \) and \( \mu^- \) has recently been calculated. 19 This calculated difference is in agreement with recent measurements 20 made with a lead, carbon and iron absorber to an accuracy of about 10%. According to the theory, for incident momenta of interest
in this experiment (1.1 to 1.5 GeV/c) the range difference $\Delta R = R_\neg - R_\pos$ varies linearly with the range $R$ such that $\Delta R/R$ is nearly constant at about $2 \times 10^{-3}$. The value of $\Delta R/R$ is nearly independent of the absorber material at these incident momenta.

The range difference correction is a major one in this experiment. The important question to be answered is how many $\mu^-$ successfully counted in the M bank while the corresponding $\mu^+$ stopped short of counting. The correction to the charge asymmetry is

$$\Delta \delta = \frac{1}{2n} \frac{dn}{dR} \Delta R$$

where $n$ is the total number of events detected and $dn/2$ is the number of $\mu^-$ stopping in $dR$ at $R$. The average incident momentum of muons which stopped near the M bank was determined to be $1290 \pm 35$ MeV/c by the Monte Carlo (which succeeds in predicting the average momentum of the total muon sample —see Fig. 11). Assigning a 4% accuracy to the range difference theory in calculating $\Delta R$ for the muons of interest we find:

$$\Delta R = 1.63 \pm 0.08 \text{ g/cm}^2 \text{ of iron.}$$

However, the major source of error in the range difference correction is lack of precise knowledge of the muon stopping distribution.
Since the N bank was not required in the $K^0_{\mu 3}$ signature, we were able to measure that $0.293 \pm 0.004$ of the accepted muons either stopped in the last steel plate or missed the N bank. The Monte Carlo prediction for this number was $0.265 \pm 0.006$, where the statistical error of the Monte Carlo has been indicated. Hence the prediction was correct to a systematic accuracy of 10%. The Monte Carlo was then used to extrapolate this measured value of $\Delta n/n$ for the whole steel plate to the value of

$$\Delta \delta = (31 \pm 7) \times 10^{-4}$$

for the $\mu^-$ stopping in the first 1.63 g/cm$^2$ of the plate. We note from Fig. 10 that the Monte Carlo successfully describes the multiple scattering in the lead wall.

2. End-of-Range Differences

Positive and negative muons behave differently at the end of their range. For this correction the most important muons are those which stopped in the 5 cm steel plate between the L and M counters, but originated from a $K^0_{\mu 3}$ decay satisfying all upstream $K^0_{\mu 3}$ signature criteria. The ratio of the number of such muons to the number of muons associated with events which passed all signature criteria is $0.30 \pm 0.03$ according to the Monte Carlo. Secondaries associated with the muons which stopped in this plate could have reached the M bank, thereby completing the signature requirements. A bias on the charge asymmetry results from asymmetrical completion of these requirements.

When a $\mu^+$ stops in the above plate, it decays to an $e^+$ with a lifetime of 2.2 microseconds. A $\mu^-$, however, cascades into the lowest Bohr orbit around an iron nucleus, where it is subject to capture as well as
decay. The decay probability of the $\mu^-$ in a bound state is nearly the same as that of a free muon.$^{22}$ However, due to the large capture probability, the lifetime of a $\mu^-$ in the first Bohr orbit about an iron nucleus is only 200 nsec.$^{23}$ The net effect of $\mu^\pm$ decaying to $e^\pm$ is negligible. The main bias on the charge asymmetry caused by end-of-the-range effects is due to mu-mesic x rays produced during the cascade into the first Bohr orbit for iron. Essentially all $\mu^-$ that are stopped produce such an x ray well within the 15 nsec sensitive time.$^{24}$ The energies and relative intensities of these x rays are listed in Table V.$^{25}$ (Here $K_\alpha, K_\beta, K_\gamma$ refer to the $2P \rightarrow 1S$, $3P \rightarrow 1S$, and $nP \rightarrow 1S$ transitions, where $n > 3$). The efficiencies for detecting these x rays in the M counters were calculated from the Klein-Nishina formula as given by Rossi.$^{26}$ The main source of uncertainty in this calculation is the lack of exact knowledge of the threshold of the M counters. This average threshold was determined to be $0.8 \pm 0.1$ MeV from the known pulse heights for minimum-ionizing particles. The detection efficiency for the $K_\alpha$ x ray is particularly sensitive to this threshold value. The absorption lengths of the cascade x rays in iron were also calculated from the Klein-Nishina formula. The results of the calculations are presented in Table VI. The total correction to the charge asymmetry from cascade x rays is then:

$$\Delta^x_{\text{x rays}} = +(3.94^{+0.96}_{-1.45}) \times 10^{-4}.$$  

The mean numbers of gamma rays$^{27}$ and neutrons emitted from an iron nucleus after $\mu^-$ capture are not well known. The absorption length of a neutron (3 to 30 MeV) in iron is about the same (35 g/cm$^2$) as the
absorption length for a 1.5 MeV gamma ray, but the detection efficiency for such neutrons in the M bank is only about 0.7%. A reasonable assumption is that about 1 neutron and about 1 gamma ray are emitted after each \( \mu^- \) capture. This is the equivalent of about 1.3 gamma rays. A correction for secondaries emitted from the nucleus after \( \mu^- \) capture would then be:

\[
\Delta \delta \approx 1.3 \times \frac{15 \text{ nsec}}{200 \text{ nsec}} \times 3.9 \times 10^{-4} = 4 \times 10^{-5}.
\]

This correction is negligible, but in order to take its uncertainty into account we symmetrize the error of the correction for x rays:

\[
\Delta \delta_{\text{end-of-range}} = + (3.9 \pm 1.5) \times 10^{-4}.
\]
V. SUMMARY

The $K^0_{\mu 3}$ charge asymmetry is determined as shown in Table VII. The systematic errors are to be interpreted as one standard deviation. Since the correlations among the corrections are believed to be insignificant, the errors are combined in quadrature to yield:

$$\delta = (6.0 \pm 1.4) \times 10^{-3}.$$
VI. ACKNOWLEDGMENT

Dr. M. Paciotti provided help in setting up the experiment, as well as valuable advice at several important stages. Dr. R. Johnson's help in the understanding of several small corrections is gratefully acknowledged. The constant encouragement of Dr. K. Crowe was important during the analysis phase. One of us (R. L. M.) was supported in part by a National Science Foundation Graduate Fellowship. The technical assistance of J. Majors and M. Donnell is also acknowledged. Finally, we wish to thank the Bevatron operating and support staff, the Math and Computing group, and the Electronics Support staff of the Lawrence Berkeley Laboratory. This work was done under the auspices of the U. S. Atomic Energy Commission.

1. The neglect of electromagnetic final-state interactions has been discussed by C. Ryan, Phys. Rev. D, 299 (1970). Our detection efficiency was not uniform over the Dalitz plot but was weighted toward high muon and pion energies in the K meson rest frame. Hence this assumption may not be valid if CP violation occurs in the electromagnetic interaction.

2. \( x_I = \frac{\langle \pi^- \pi^+ \nu | H_w | K^0 \rangle}{\langle \pi^- \pi^+ \nu | H_w | K^0 \rangle} \). The phase of \( x_I \) is defined by the fact that \( |K^0\rangle = (|K^0\rangle - |\bar{K}^0\rangle)/\sqrt{2} \) has CP = - 1. The definition of \( x_I \) can be generalized to include dependence on the Dalitz plot parameters and lepton helicities; see L. M. Sehgal, Phys. Rev. Letters 21, 412 (1968).

3. This experiment is discussed in greater detail by R.L. McCarthy (Ph. D thesis), University of California, Berkeley; available as Lawrence Berkeley Laboratory Report LBL-550 (1971), unpublished.

4. M. A. Paciotti (Ph.D. thesis), University of California, Berkeley; available as Lawrence Radiation Laboratory Report UCRL-19446 (1970), unpublished. This is a reanalysis of the data of D. Dorfan et al., Phys. Rev. Letters 19, 987 (1967). We have used the prescription in Paciotti's thesis (p. 56) to correct for the range differences between \( \mu^+ \) and \( \mu^- \).

6. The superweak theory as presented by T. D. Lee and L. Wolfenstein, Phys. Rev. 138B1490 (1965), predicts $\epsilon = \eta_{+} = \eta_{00}$ and $\arg \epsilon = \tan^{-1}(2\Delta m_\tau)$. Hence $2\Re \epsilon = 2|\eta_{+}| \cos(\arg \epsilon)$. We take $|\eta_{+}| = (1.91 \pm 0.06) \times 10^{-3}$ from V. Fitch et al., Phys. Rev. 164, 1711 (1967). We also take $\tan^{-1}(2\Delta m_\tau) = (43.2 \pm 0.4)^{\circ}$ from S. H. Aronson et al., Phys. Rev. Letters 25, 1057 (1970).

8. $\Re(x_\mu) = 0.19^{+0.13}_{-0.18}$ and $\Im(x_\mu) = -0.12^{+0.20}_{-0.17}$ from B. Webber et al., Phys. Rev. D3, 71 (1971). Also, $\Re(x_\nu) = 0.04^{+0.10}_{-0.13}$ and $\Im(x_\nu) = 0.12^{+0.17}_{-0.16}$ from M. F. Graham et al., Il Nuovo Cimento 9A, N.2, 166 (1972).

12. The angular dependence was assumed to be $\exp(-3.9 P \theta)$, where $P$ is the $K^0_L$ momentum in GeV/c and $\theta$ is the production angle, as given by G. Trilling, 200 Bev Accelerator: Studies on Experimental Use 1964-1965, Lawrence Radiation Laboratory Report UCRL-16830, Vol. 1, p. 38, unpublished.
