ABSTRACT

We describe the design of a table-top pulsed x-ray system for measuring fluorescent lifetime and wavelength spectra of samples in both crystal and powdered form. The novel element of the system is a light-excited x-ray tube with a tungsten anode at +30 kV potential. The S-20 photocathode is excited by a laser diode with a maximum rate of 10 MHz, each pulse having <100 ps fwhm (full-width at half-maximum) and >10⁷ photons. In a collimated 2 mm x 2 mm beam spot 40 mm from the anode we expect >1 x-ray per pulse. A sample is exposed to these x-rays and fluorescent photons are detected by a microchannel PMT with a photoelectron transit time spread of 60 ps fwhm, a sapphire window, and a bialkali photocathode (wavelength range 180-600 nm). The combined time spread of a laser diode, the x-ray tube, and a microchannel tube has been measured to be 109 ps fwhm. To measure wavelength spectra, a reflection grating monochromator is placed between the sample and the PMT.

1 BACKGROUND AND INTRODUCTION

In previous work, an electron synchrotron was used in single-bunch mode to measure the x-ray excited fluorescence of over 400 compounds. Interesting fluorescence emissions were detected from several compounds by this method, including CeF₃, PbCO₃, PbSO₄, Yb₂O₃, CeCl₃, BaCl₂, and CuI [1, 2]. At the same time, a light-excited x-ray tube was developed for producing very brief (<100 ps) pulses of x-rays (Figure 1) [3].

In this work, we describe the design of a table-top pulsed x-ray fluorescence measurement system using a laser diode and a light-excited x-ray tube. This system has a number of advantages over the electron synchrotron technique. Among these are (i) measuring samples without having to transport personnel and equipment to a remote site, (ii) measuring samples immediately rather than waiting for the next single-bunch beam run, (iii) a narrower x-ray pulse width (<100 ps), and (iv) the ability to vary the excitation repetition period from 100 ns to well beyond 10 μs.

The method of Bollinger and Thomas [4] (as modified by Moszynski and Bengtson [5] for coincident 511 keV annihilation photons) is also used to measure fluorescent decay spectra. However, the timing accuracy is limited to about 200 ps fwhm by jitter in the trigger scintillator, and it is difficult to determine the fraction of slow components.

2 PULSED X-RAY SOURCE

2.1 Laser Diode

The PLP-01 Picosecond Light Pulser consists of a controller and a laser diode head. The pulse width and number of photons per pulse depend only weakly on the pulse rate, which can be varied from 1 Hz to 10 MHz. Each light pulse is preceded by a timing pulse with a time jitter of ±10 ps. In addition, the laser diode can be externally triggered or operated in dc mode. See Table 1 for additional details.

2.2 Light-excited X-ray Tube

The light-excited x-ray tube (Figure 1), is essentially a single-stage photomultiplier tube. It has an S-20 photocathode at ground potential and a tungsten anode at +30 kV. Light liberates photoelectrons at the photocathode, which are accelerated to 30 keV to strike the tungsten target, producing bremsstrahlung x-rays. The photocathode to anode transit time is 0.8 ns and the anode surface is oriented at 45° with respect to the incident electron beam. See Table 2 for additional details.

The maximum anode current of 50 µA corresponds to a maximum photon rate of $3 \times 10^{15}$/s at 10% quantum efficiency. At 10 MHz and $2 \times 10^7$ photons per pulse, the laser diode will provide $2 \times 10^{14}$ photons/s.

Table 2. Characteristics of Hamamatsu N5084 Light-excited X-Ray Tube

| Overall tube length | 152 mm |
| Tube Diameter       | 52 mm  |
| Photocathode        | S-20   |
| Quantum efficiency @ 650 nm | > 10% |
| Photocathode diameter | 12 mm  |
| Target material (anode) | Tungsten (45°) |
| Output window material | Beryllium |
| Output window diameter | 20 mm  |
| Output window thickness | 0.5 mm |
| Cooling              | Natural air |
| Tube voltage (max)   | 30 kV  |
| Tube current (max)   | 50 µA  |
| Photocathode photon rate (max) | $3 \times 10^{15}$/s @ 10% QE |

3 RESULTS

3.1 Measurement of Timing Response

The light-excited x-ray tube was tested by illuminating its photocathode with laser diode pulses and measuring the x-rays with a Be-window microchannel electron multiplier (Figure 2). The laser diode was coupled to the x-ray tube with an optical fiber. The measured time distribution of detected x-rays is shown in Figure 3. The 109 ps fwhm includes three components: the width of the laser diode pulses (55 ps), time spread in the light-excited x-ray tube, and the timing resolution of the microchannel tube (57 ps). The contribution of the light-excited x-ray tube is inferred to be 75 ps.

3.2 System for Fluorescence Measurements

Figure 4 shows the system for measuring fluorescence decay timing spectra from powder or crystal samples. The delayed coincidence method is used to record the time distribution between the x-ray pulses and the individual fluorescent photons.

The laser diode head is proximity coupled to the x-ray tube photocathode for maximum photon rate. The microchannel PMT has a bialkali photocathode, a sapphire window, a wavelength range from 180 to 600 nm, and a 60 ps transit time spread. The PMT is thermoelectrically cooled to -20°C to reduce the dark rate to a few photoelectrons/s.

Emission spectra can be measured by inserting a monochromator between the sample and the microchannel phototube. To extend the upper limit to 900 nm, a phototube with a quartz window, a GaAs photocathode, and 4 ns transit time spread can be used.

The sample chamber is evacuated to a pressure below $10^{-3}$ mm Hg to avoid fluorescence from air. A current meter at the photocathode is used to monitor the photoelectron current and a current meter at the power supply is used to monitor the sum of the anode current and any leakage currents to ground.
3.3 Data Acquisition and Analysis

Time differences between the x-ray excitation and the arrival of fluorescent photons are digitized by a time to digital converter (TDC) with a bin width of 50 ps and a maximum dynamic range of 800 μs, corresponding to the maximum 24-bit CAMAC data number. The TDC can detect multiple photon detections in the conversion time range, and these events are rejected to reduce bias and permit substantially higher data rates [6]. A compression algorithm preserves the 50 ps bin width near the time of the excitation but combines data into progressively wider bins at later times. In a typical case, $2 \times 10^5$ bins spanning a 10 μs conversion range are compressed into $2 \times 10^3$ bins for fitting. The fitting program determines fractions, decay times, and rise times of fluorescent components by fitting a sum of exponentials (convolved with the system timing response) to the compressed data [7].

4 CONCLUSIONS

By combining a state-of-the-art laser diode and a recently developed light-excited x-ray tube, we have designed a tabletop system for measuring fluorescent intensities and decay times with a timing accuracy of about 100 ps. The data acquisition uses photon counting and signal averaging, so that accurate measurements are possible for even weakly fluorescing samples. The system is more accurate than methods using coincident nuclear radiation and more accurate and convenient than methods using synchrotron x-radiation.

5 ACKNOWLEDGEMENTS

We would like to thank J. Cahoon and T. Vuletich for technical assistance, R. Muller for technical coordination, and P. Rentzepis and K. Kaufmann for helpful discussions.
