Abstract

Gluon fusion is the main production mechanism for Higgs bosons with masses up to several hundred GeV in pp collisions at LHC and SSC. We present the QCD corrections to the fusion cross section for arbitrary Higgs and top mass values: \( gg \rightarrow H(g) \), \( gg \rightarrow Hq \) and \( q\bar{q} \rightarrow Hq \). The QCD corrections are positive and they increase the cross section \( \sigma(pp \rightarrow H) \) by about a factor 1.5 to 1.7. The analysis applies to the production of Higgs particles in the Standard Model and also to the production of the CP-even Higgs particles in extensions of the Higgs sector as required for example by supersymmetric theories.

Most of the building blocks of the Standard Model have been tested to a very high precision in recent years. However, the Higgs mechanism [1], one of the cornerstones of this theory, has not yet been proven experimentally to be the basic mechanism for the generation of the fundamental particle masses. To accommodate the well-established electromagnetic and weak phenomena, this mechanism requires the existence of at least one weak isodoublet scalar field of which one degree of freedom manifests itself as a real physical particle for small enough masses. The discovery of the Higgs particle is the experimentum crucis for the canonical formulation of the electroweak interactions.

Theoretical consistency restricts the mass of the Higgs boson in the Standard Model to less than about 700 GeV [2]. Higher mass values may nevertheless be realised in extensions of the (canonical) Standard Model. A lower limit of about 60 GeV has been set by the LEP experiments [3]. Depending on the maximum energy LEP will reach, the search for Higgs particles can eventually be extended up to masses of about 90 GeV. To continue the search beyond this limit, new accelerators are needed. While e+e−-colliders with a c.m. energy of 500 GeV are ideal machines to investigate Higgs particles in the intermediate mass range below the ZZ decay threshold, the multi-TeV pp colliders LHC and SSC can sweep the mass range up to the theoretical upper limit [4].

For Higgs boson masses up to \( \sim 700 \) GeV the dominant production mechanism in high-energy proton-proton collisions is gluon-gluon fusion [5]. The Higgs bosons couple to gluons through a heavy-quark triangle loop. In this note we present the QCD corrections to the cross section \( \sigma(pp \rightarrow H+X) \) of the fusion process,

\[
\begin{align*}
gg & \rightarrow H(g) \quad \text{and} \quad gg \rightarrow Hq, \quad q\bar{q} \rightarrow Hg
\end{align*}
\]

for arbitrary Higgs boson and loop quark masses, Fig. 1. This analysis extends previous work of Refs [6] and [7] in which the Higgs boson mass was assumed to be much smaller than the loop-quark mass. The analysis of the next-to-leading order QCD corrections to the Higgs production cross section is required for two reasons: (i) The lowest order prediction of the cross section \( \sigma(pp \rightarrow H) \) depends strongly on the renormalization and factorization scales. The next-to-leading order stabilizes the prediction and leaves us only with a mild residual dependence on these parameters. (ii) Since the QCD corrections turn out to be positive and large, the calculation is a posteriori also of high experimental significance. The transverse momentum spectra of the Higgs bosons have been considered at various levels of theoretical refinement in Refs [8].

Heavy quarks \( Q \) provide the dominant contribution to the coupling of Higgs bosons to gluons. Neglecting finite-width effects, the cross section for the production of Higgs particles in pp collisions is given to lowest order (Fig. 1a) by [5,6,7]

\[
\sigma_{LO}(pp \rightarrow H+X) = \sigma_{H} \frac{dC_{gg}}{dy}
\]

with

\[
\begin{align*}
\sigma_{H} &= \frac{G_{F}a_{Q}}{288\sqrt{\pi}} \left[ \frac{3}{2} v_{Q}^{-1} \left[ 1 + (1 - v_{Q}^{-1}) f(\tau_{Q}) \right] \right]^{2} \\
\tau_{Q} &= \frac{m_{H}^{2}}{4m_{Q}^{2}}
\end{align*}
\]

and \( dC_{gg}/dy \) denoting the gluon luminosity. The scaling variables are as usual defined by \( \tau_{Q} = m_{Q}^{2}/4m_{H}^{2} \) and \( \tau_{g} = m_{g}^{2}/s \) where \( s \) is the total c.m. energy of the proton collider.

The QCD corrections to the lowest order diagram (1a) consist of gluon-quark and Higgs-quark vertex corrections, propagator corrections and the associated counter terms. An example
is shown in Fig. 1b. The renormalization program has been carried out in the MS scheme. The mass $m_Q$ of the heavy quark is defined at the pole of the quark propagator. The renormalization of the Higgs-quark vertex is connected with the renormalization of the quark mass and the quark wave function, $Z_{qqQ} = Z_Q - 4m_Q/m_Q [9]$. In addition to these virtual corrections, the gluon radiation off the initial state gluons and off the heavy-quark loop must be taken into account, Fig. 1c. After adding up these corrections, ultraviolet and infrared singularities cancel. Left-over collinear singularities are absorbed into the renormalized parton densities [10] which we define in the MS scheme. Finally the subprocesses $gQ \rightarrow Hq$ and $q\bar{q} \rightarrow Hq$ must be added, Fig. 1d.

The result for the cross section can be cast into the following form:

$$
\sigma(pp \rightarrow H + X) = \sigma_0 \left[ 1 + C(t_Q) \alpha_s \right] r_H \frac{d\mathcal{L}_{ee}}{d\mathcal{t}_H} + \Delta \sigma_{ee} + \Delta \sigma_{qg} + \Delta \sigma_{q\bar{q}},
$$

(4)

The coefficient $C(t_Q)$ denotes the contribution from the virtual two-loop corrections regularized by the infrared singular part of the cross section for real gluon emission. This coefficient splits into the infrared term ($\alpha_s$), a term depending on the renormalization scale $\mu$ and a $t_Q$ dependent piece $c(t_Q)$,

$$
C(t_Q) = \alpha_s^2 + c(t_Q) + \frac{32 - 2NF}{6} \log \frac{\mu^2}{m_H^2},
$$

(5)

The term $c(t_Q)$ can be reduced analytically to a 2-dimensional Feynman-parameter integral which has been performed numerically [11,12]. In the heavy quark limit $r = m_H^2/4m_Q^2 \ll 1$, the coefficient approaches the value $c(t_Q) \rightarrow \frac{1}{18}$ [6,7].

The (non-singular) contributions from gluon radiation in $gg$ scattering, from $q\bar{q}$ scattering and $q\bar{q}$ annihilation depend on the renormalization scale $\mu$ and on the factorization scale $\Lambda$ of the parton densities (Figs.1b-d),

$$
\Delta \sigma_{ee} = \int_{t_H} d\mathcal{t}_H \frac{d\mathcal{L}_{ee}}{d\mathcal{t}_H} \delta(\mu^2) \left[ -z P_{gg}(z) \log \frac{\mu^2}{x_T^2} + d_{eg}(z, t_Q) \right]
$$

$$
+ 12 \left[ \left( \frac{\log(1-z)}{1-z} + \frac{z}{2} \log(1-z) \right) \log(1-z) \right]
$$

$$
\Delta \sigma_{qg} = \int_{t_H} d\mathcal{t}_H \sum_q \frac{d\mathcal{L}_{qg}}{d\mathcal{t}_H} \delta(\mu^2) \left[ \frac{1}{2} \log \frac{M^2}{x_T} + \log(1-z) \right] z P_{qg}(z) + d_{eg}(z, t_Q)
$$

$$
\Delta \sigma_{q\bar{q}} = \int_{t_H} d\mathcal{t}_H \sum_q \frac{d\mathcal{L}_{q\bar{q}}}{d\mathcal{t}_H} \delta(\mu^2) d_{q\bar{q}}(z, t_Q)
$$

with $z = t_Q/r$. The renormalization scale enters through $\alpha_s(\mu^2)$ and $\alpha_s(\mu^2)$. $P_{gg}$ and $P_{qg}$ are the standard Altarelli-Parisi $g \rightarrow g$ and $q \rightarrow g$ splitting functions [13]. $P_a$ denotes the usual distribution such that $F(x) = F(z) - \delta(x-1) f_d F(z)$. The coefficients $d_{eg}$, $d_{gq}$ and $d_{q\bar{q}}$ can be reduced to 1-dimensional integrals which have been evaluated numerically [12]. In the heavy quark limit, the coefficients can be determined analytically [6,7], $d_{gg} \rightarrow -\frac{1}{10}(1-z)^3$, $d_{gq} \rightarrow -1 + 2z - \frac{1}{2}z^2$ and $d_{q\bar{q}} \rightarrow \frac{3}{20}(1-z)^3$.

The final results of our analysis are presented in Figs. 2 and 3 for LHC $\sqrt{s} = 16$ TeV and SSC $\sqrt{s} = 40$ TeV energies. They are based on a top quark mass of 140 GeV and, if not stated otherwise, on the DFLM parametrization [14] for the parton densities. These parton densities have been transformed into the MS scheme with a factor $\Lambda(\mu) = 207$ MeV for $N_f=5$ quark flavors. The scale dependence of the QCD coupling $a_s(\mu^2)$ is used in next-to-leading order, with the standard matching condition [15] at $\mu = m_H$. The cross section is sensitive to gluon and quark densities at a value of order $10^{-2}$ to $10^{-3}$ so that subtle non-linear effects in the evolution at small $z$ need not be taken into account yet. More technical details will be described in a forthcoming publication.

We introduce $K$ factors in the standard way, $K_{\text{LO}} = \sigma_{LO}/\sigma_{OO}$, $K_{\text{NNLO}}$ with the cross sections in next-to-leading order are normalized to the cross sections $\sigma_{LO}$, evaluated for parton densities and $\alpha_s$ in leading order. $K_{\text{LO}}$ accounts for the [regularized] virtual corrections, $K_{\text{NNLO}}$ for the real corrections, both defined in eqs. (4),(5),(6). The $K$ factors are shown for LHC and SSC energies in Figs. 2 as functions of the Higgs mass. For both the renormalization and the factorization scale $\mu = M = m_H$ has been chosen. Apparently $K_{\text{LO}}$ and $K_{\text{NNLO}}$ are of the same size and of the order of 60% while $K_{\text{NP}}$ and $K_{\text{QQ}}$ are quite small. Apart from the threshold region for Higgs decays into $f$ pairs, $K_{\text{LO}}$ is insensitive to the Higgs mass. The absolute magnitude of the correction is positive and large, increasing the cross section for Higgs production at pp colliders significantly by about a factor $1.5$ to $1.7$. Comparing the exact numerical results with the analytic expressions in the heavy quark limit, it turns out that these asymptotic solutions provide an excellent approximation even for Higgs masses above the top decay threshold. For Higgs masses below $700$ GeV, the deviations of the QCD corrections from the asymptotic approximation are less than 15%.

The [unphysical] variation of the cross section with the renormalization and factorisation scales is significantly reduced by including the next-to-leading corrections. While for $m_H = 500$ GeV and $\sqrt{s} = 16$ TeV, for instance, the ratio $\sigma_{LO}/\sigma_{NLO}$ is found to be 1.63 [DFLM-LO [14] parametrization of the parton densities], this ratio drops to 1.32 in the next-to-leading order approximation. For $\sqrt{s} = 40$ TeV this ratio falls from 1.42 down to 1.23. Besides the residual scale dependence, the main uncertainty in the prediction of the Higgs production cross section is due to the gluon density. Adopting a set of representative parton parametrisations [14,16], we find a variation of about 40% between the maximum and minimum value of the cross section for Higgs mass values above $100$ GeV. This uncertainty will be reduced drastically in the near future when new data will become available from deep inelastic lepton-nucleon scattering experiments, in particular at HERA.

Though the analysis has been carried out in detail for the production of Higgs bosons in the Standard Model, it is clear that the results can readily be transcribed, mutatis mutandis, to all other CP-even Higgs bosons in extended Higgs sectors. A well-known example is provided by the minimal supersymmetric extension of the Standard Model in which two Higgs doublets lead to two neutral CP-even particles $h, H$ and a CP-odd particle $A$. Depending on the Higgs-fermion coupling, triangle b-quark loops may provide major contributions to the effective Higgs-gluon-gluon couplings [17]. Since, apart from minor corrections, the $K$ factors are determined by the ratio of the Higgs to the quark-loop mass, the results in Fig. 2 can directly be reinterpreted for $h, H$ production after renormalizing the $m_H$ axis by the factor $m_H/m_t$ for b loops. The cross section for the Higgs boson $A$ requires a careful reanalysis of the effective CP-odd vertex.
Acknowledgements. We have greatly benefitted from discussions with M. Chanowitz, S. Ellis, I. Hinchliffe, J. Kühn, Z. Kunst and J. van der Bij. DG thanks I. Hinchliffe for the warm hospitality extended to him at the Lawrence Berkeley Laboratory.

[11] The analytic functions which have been integrated numerically, include singularities like \( \log(x+ic) \) and \( 1/(x+ic) \). The integrals have been solved for small positive \( c \) values varied from \( 10^{-2} \) downward. At \( 10^{-3} \) a plateau was reached which extends down to \( 10^{-4} \). Below this value, the numerical integration became unstable.
