Title
Generation of Initial Kinetic Distributions for Simulation of Long-Pulse Charged Particle Beams with High Space-Charge intensity

Self-consistent Vlasov-Poisson simulations of beams with high space-charge intensity often require specification of initial phase-space distributions that reflect properties of a beam that is well adapted to the transport channel — both in terms of low-order rms (envelope) properties as well as the higher-order phase-space structure. Here, we first review broad classes of kinetic distributions commonly in use as initial Vlasov distributions in simulations of unbunched or weakly bunched beams with intense space-charge fields including: the Kapchinskij-Vladimirskij (KV) equilibrium, continuous-focusing equilibria with specific detailed examples, and various non-equilibrium distributions, such as the semi-Gaussian distribution and distributions formed from specified functions of linear-field Courant-Snyder invariants. Important practical details necessary to specify these distributions in terms of usual accelerator inputs are presented in a unified format. Building on this presentation, a new class of approximate initial kinetic distributions are constructed using transformations that preserve linear-focusing single-particle Courant-Snyder invariants to map initial continuous-focusing equilibrium distributions to a form more appropriate for non-continuous focusing channels. Self-consistent particle-in-cell simulations are employed to show that the approximate initial distributions generated in this manner are better adapted to the focusing channels for beams with high space-charge intensity. This improved capability enables simulation applications that more precisely probe intrinsic stability properties and machine performance.

I. INTRODUCTION

Vlasov numerical simulations of charged particle beams have become an indispensable tool to analyze long-pulse accelerator systems with high space-charge intensity\cite{1-11}. Analytical theory can become exceedingly cumbersome for realistic investigations of systems with strong space-charge forces. Meanwhile, the increasing power of digital computers and ever improving numerical methods enable high-level modeling with lesser degrees of idealization. Large-scale computer simulations of Vlasov evolutions using particle-in-cell (PIC) methods adapted from plasma physics\cite{12, 13} are routinely used to identify physical mechanisms limiting transport\cite{14-16}, to validate practical design concepts\cite{17}, and to support interpretation of experiments where only limited diagnostics are possible\cite{5, 18, 19}. In the future, direct Vlasov methods promise improved, low-noise simulations for improved understanding of halo particle production and other effects difficult to resolve with PIC methods\cite{20-23}. It is critical in many applications of Vlasov simulations of intense beams to employ initial ("load") distribution functions that are well adapted to the transport lattice. If the total beam propagation distance is not too long and the injector is amenable to modeling, then the beam emission from the source can be simulated and the subsequent evolution through the transport and acceleration cycle of the machine simulated for high-level "first-principles" modeling with limited assumptions\cite{24-27}. Alternatively, the loaded distribution can be synthesized based on reasonable extrapolations of limited experimental measurements of the beam phase-space at a diagnostic location in the machine lattice\cite{28, 29}. Or finally, the initial beam distribution can be assumed to be of a particular (ansatz) form motivated by physical insight or generated by relaxation processes from a relatively simple initial ansatz distribution. The ansatz approach is especially useful when analyzing intrinsic transport limits of beams with high space-charge intensity — particularly if a smooth equilibrium beam distribution can be constructed. Then well-established methods of plasma physics\cite{30} can be applied to understand the consequence of system perturbations in a simplified manner.

In continuous-focusing channels the transverse applied-focusing force is constant as the beam propagates in the lattice. System energy is then conserved and an infinite variety of smooth, stable equilibrium distributions with appealing physical properties can be constructed from distributions that are specified functions of the single-particle Hamiltonian\cite{30-32}. At high space-charge intensity, the self-consistent space-charge forces of the continuous-focusing distributions lead to characteristic Debye-screened density projections that one would expect on physical grounds — with a flat core and a sharp edge\cite{30-32}. Unfortunately, the continuous-focusing model is not in general directly applicable to laboratory systems. Real applied-focusing lattices are typically periodic or quasi-periodic structures where the applied forces vary rapidly with the axial coordinate $s$. This variation of the applied-focusing force vastly complicates the construction of equilibrium or approximate equilibrium distributions and also complicates beam stability\cite{15, 33-35}. The $s$-varying applied-focusing fields can pump energy into and out of the beam, rendering the continuous-focusing model only useful as a rough, qualitative guide for lattices with relatively weak applied-focusing (i.e., low undepressed particle phase-advances).

In the presence of finite beam space-charge, a well-known self-consistent transverse equilibrium distribution for a linear applied-focusing channel with arbitrary $s$-variations in the focusing forces is the Kapchinskij-Vladimirskij (KV) distribution\cite{30-32, 36}. Although the low-order properties of the KV distribution are appealing physically, the full
four-dimensional structure corresponds to a singular, hyper-ellipsoidal shell in phase-space. For strong space-charge, this singular structure drives unphysical, higher-order instabilities [31, 32, 37–44] which limit practical use of the KV distribution for initializing simulations. The KV distribution is the only exact Vlasov equilibrium known that is a function of linear-field Courant-Snyder invariants [45]. Recent work by Danilov et al. [46] suggest alternative classes of exact kinetic equilibrium distributions for linear forces. These distributions are singular and based on elementary plasma physics considerations are expected to be similarly unstable as the KV distribution in regimes of high space-charge strength.

Due to the limitations of the singular equilibrium distributions (KV or otherwise) and the lack of known smooth equilibria for focusing channels with s-varying applied-focusing forces, a number of approaches to generate initial Vlasov distributions for simulations have been taken by assuming specific non-equilibrium forms. One common such distribution is the so-called Semi-Gaussian distribution which retains the uniform charge-density of the KV model within an elliptical envelope but modifies the local temperature to be Gaussian-distributed and spatially uniform [47]. This results in a beam edge that is not locally in force balance and a spectrum of waves are launched [15, 48, 49].

Depending on the application, such waves may or may not pose a problem. Another approach employed is to initialize beams that are functions of Courant-Snyder invariants of single-particle orbits in the applied-focusing fields [50, 51]. Such distributions are equilibria when space-charge forces are negligible but can launch significant collective waves due to the lack of consistent local force-balance in the core of the beam when space-charge forces are a significant fraction of the average applied-focus forces. Procedures have been developed to partially circumvent this problem by gradually increasing the space-charge intensity by adjusting species weights while evolving the beam [52, 53], or similarly by slowly removing nonlinear applied-field components applied to better match the edge while evolving the beam [54]. The intent behind such methods is to allow phase-mixing, nonlinear effects, and collective relaxation processes to effectively relax the core of the beam producing an “initial” distribution better adapted to the applied-focusing channel. Unfortunately, it can be difficult to parametrically determine sufficient propagation distances and criteria to specify adequate relaxation [14] and/or how rapidly the space-charge intensity can be increased toward desired values. Moreover, the desired beam parameters (emittances, etc.) can be difficult to obtain. Yet another approach has been to employ “Langevin” procedures where stochastic, scattering terms and damping terms are added to the particle equations of motion and the simulations are advanced until these terms balance while driving the beam to a relaxed state [55]. Such methods can again be difficult to tune to achieve desired beam parameters and may be most applicable to continuous focusing models. Finally, several perturbative theories based on Hamiltonian averaging techniques [32, 56–61] and canonical transformations [62] have been developed to construct approximate, non-KV beam equilibria in s-varying focusing channels. It is expected that the Hamiltonian averaging techniques should produce increasingly reliable equilibrium representations as the strength of the applied-focusing lattice decreases. The Hamiltonian averaged methods have yet to be implemented and tested in self-consistent Vlasov simulations, but promise increased performance if perturbative expansions are carried out to sufficient order and necessary back transformations are made to generate loads. Vlasov simulations of the canonical transformation procedure of Ref. [62] have been carried out and appear to verify near-equilibrium structure for solenoidal periodic-focusing channels but not for strong (quadrupole) periodic-focusing.

In this study, conventional initial distributions employed in beam simulations are first reviewed within a common framework. Special attention is applied to generating smooth equilibria in continuous-focusing channels. Continuous equilibria with “waterbag,” “parabolic,” and “thermal” forms are analyzed in detail. Procedures are formulated for all types of distributions presented to initialize macro-particles in PIC simulations. Results from these standard distributions are then applied to develop a new class of pseudo-equilibrium distributions that are useful for initializing Vlasov simulations of beams in transport channels with s-varying applied-focusing forces. The pseudo-equilibrium distributions are constructed by transforming continuous-focusing equilibria to rms-equivalency [31] with a KV beam in a manner that preserves linear space-charge Courant-Snyder invariants. The pseudo-equilibrium distributions are not exact equilibria, but are relatively easy to synthesize, and have appealing physical properties that better reflect the relaxed, equilibrium-like form expected in stable transport. The proximity to equilibrium form reduces the initial transient waves associated with the lack of full consistency, thereby simplifying interpretation of the simulations. Care is taken to formulate the procedure using standard accelerator inputs. Results are illustrated for transverse, two-dimensional (2D) PIC simulations of an unbunched, coasting beam. The results indicate that the loads will prove superior to standard beam initializations – particularly for high relative space-charge intensity. The methodology used to generate the pseudo-equilibrium distributions also applies to 3D distributions if the axial particle phase-space is specified. Parametric simulations studies carried out with initial pseudo-equilibrium distributions have already been applied to better understand the intrinsic space-charge limits in the transport of matched beams in periodic focusing channels [15, 33–35]. Parts of formulations presented have been developed through extensions of cited material in a series of graduate level classes on beam physics with high space-charge intensity taught by Barnard and Lund at the U.S. Particle Accelerator School [63] and Lund at an INRIA School [64].

The organization of this paper is the following. PIC simulation codes employed for testing loaded distributions,
along with example system and numerical parameters employed, are briefly reviewed in Sec. II. Standard classes of
transverse distributions commonly employed in simulations are summarized in Sec. III including: equilibrium KV
and continuous-focusing distributions, and nonequilibrium semi-Gaussian and linear-field Courant-Snyder invariant
distributions. Important details on Courant-Snyder invariant forms and on explicit implementations of continuous-
focusing waterbag, parabolic, and thermal equilibrium distributions are given in the Appendices. These results are
applied in Sec. IV to construct classes of pseudo-equilibrium distributions. Simulation presented highlight key results.
Concluding comments in Sec. V outline the range of usefulness and limitations of the pseudo-equilibrium distributions.

II. SIMULATION DESCRIPTIONS

Here we briefly describe two electrostatic PIC simulation codes employed and parameter choices made associated
with example simulations carried out. This allows succinct presentation of later examples while providing complete
details on numerical methods and parameters employed so results can be reproduced. Methods described are mostly
standard and can be readily applied with in a variety of PIC codes used to simulate charged particle beams with high
space-charge intensity. The two codes employed to evaluate the performance of initial distributions analyzed in this
study are WARP (Sec. II A) and B-DYN (Sec. II B). Example simulations are carried out on both serial and parallel
computer systems using both codes. Code descriptions focus on specific numerical methods employed. For simplicity,
transverse simulations are carried out of a coasting beam with a common set of system parameters (Sec. II C).
Parameter discussions are framed in a general manner to highlight resolution and statistics issues associated with PIC
simulations.

A. The WARP code

The WARP code is a versatile set of simulation tools originally developed to model ion beams with intense space-
charge for application to heavy ion fusion[1, 2, 4, 65, 66]. Particle-moving, fieldsolve, loading, and diagnostic routines
are linked to a Python interpreter to enable a wide variety of simulations without modifying the source code. The
WARP code has both fully 3D, \( r - z \), and transverse 2D slice PIC packages in addition to moment package for
centroid and envelope descriptions. All PIC packages are multi-species. The transverse slice package is applied
for this study which leap-frog advances macro-particles in time with time-advance steps iterated to map particles
from slice to slice. Residence corrections are applied when particles enter and exit hard-edge quadrupole focusing
elements. The kinematics are fully relativistic and leading-order self-magnetic field effects are included by gamma-
factor corrections[32, 67, 68]. Various fieldsolvers can be applied to solve the discretized Poisson equation with detailed
conducting structures. Here we employ an Fast Fourier Transform (FFT) solver coupled with a capacity matrix solver
to implement boundary conditions for a cylindrical, conducting beam-pipe on a uniform, square grid. Symmetry
conditions can be exploited for more efficient simulations (a 4\( \times \) speed-up for ideal quadrupoles). A wide variety
of initial distributions described in this paper can be loaded as well as “first-principles” simulations of ions emitted from
space-charge limited flow injectors, and various synthesized distributions based on extrapolations of a limited set of
beam properties (usually from measured experimental data). Various ordered and pseudo-random number sequences
can be applied when generating particle loads. Diagnostics include particle phase-space projections with transforms
to remove linear coherent flows (allowing better visualization of small, nonlinear distribution distortions), and various
moment and binned quantities calculated from the distribution (standard moments as well as fluid flows, kinetic
temperatures, etc.).

B. The B-DYN code

The B-DYN code was developed to study high space-charge intensity beam dynamics during the final beam bunch-
ing section in heavy ion fusion drivers[69–71]. The B-DYN code employs a 2D, transverse slice model. When applied
to longitudinally compressing beams, species weights are adjusted to model increased transverse space-charge forces
resulting from the compression[72]. Macro-particles are advanced in the axial coordinate \( s \) using the paraxial approx-
imation, relativistic equations of motion, and the leap-frog method. Axial advance steps are chosen so that particles
are not advanced through element boundaries when entering and exiting hard-edge quadrupoles. Leading-order self-
magnetic field effects are included using gamma-factor corrections[32, 68]. The self-field is calculated on a uniform,
square grid by solving the discretized Poisson equation using a multigrid, successive over-relaxation method[73].
Conducting-pipe boundary conditions are taken on the square grid boundary. System symmetries are not exploited.
A wide variety of distributions can be loaded. Sequences of pseudo-random numbers are employed in generating particle loads.

C. Simulation Parameters

In simulations carried out to illustrate distribution loads, we assume a periodic focusing-off-defocusing-off (FODO) quadrupole magnetic-focusing lattice or a continuous-focusing lattice. The periodic FODO lattice has piecewise constant lattice focusing-functions $\kappa_j$ in the $j = x, y$ planes as illustrated in Fig. 1 with $\kappa_x = -\kappa_y$. Quadrupole focusing elements have fractional magnet occupancy $\eta$ in the lattice with period $L_p = 0.5$ m. Equal axial-length and equal-strength focusing and defocusing quadrupoles ($\ell = \eta L_p/2$) are separated by equal axial-length drifts $[d = (1 - \eta)L_p/2]$. The scale of the $\kappa_j$ are set by the undepressed particle phase-advance $\sigma_0$ (measured in degrees) using a formula presented in Ref. [74] ($\sigma_{0x} = \sigma_{0y} \equiv \sigma_0$) for $\sigma_0 = 45^\circ$ (for relatively weak focusing), and $\sigma_0 = 70^\circ$ (for relatively strong focusing near the stability limit of the lattice[15, 33–35]). A pure $K^+$ ion beam is assumed with $E_b = 1$ MeV axial particle kinetic energy (nonrelativistic). No spread in axial velocity is taken for simplicity, and the beam is unbunched and coasting (not accelerating) in the periodic lattice. The rms-edge emittance of the beam is set as $\varepsilon_x = \varepsilon_y = 50$ mm mrad [see Eq. (24)] for both strengths of applied-focusing fields considered. The beam line-charge $\lambda = \text{const}$ is adjusted to obtain specified values of the dimensionless perveance $Q$ [see Eq. (22)]. The initial beam envelope is taken to be rms-matched in the lattice according to the KV envelope equations [see Eq. (21)], and the beam slice is launched at the axial midpoint of a drift before a focusing-in-$x$ quadrupole. Depressed particle phase-advances $\sigma$ ($\sigma_x = \sigma_y \equiv \sigma$) are specified for the loaded beam with nonuniform charge-density in terms of $\sigma/\sigma_0$, calculated from an rms-equivalent matched beam[31] [see Eq. (25)].

For continuous-focusing simulations, the same choices described above for the FODO quadrupole lattice are made, but the applied-focusing functions are set with $\kappa_j = k_{j0}^2 = \text{const}$. To further aid comparisons to FODO lattice simulations, we take (arbitrarily) $k_{j0} = (\pi/180^\circ)\sigma_0/L_p$ with $L_p = 0.5$ m.

Numerical parameters of the simulations are set for both high resolution and good statistics (low noise) to better evaluate the subsequent evolution of the distribution loads. Parameter choices are specified for loaded distributions with nonuniform space-charge in terms of rms-equivalent beam[31] edge radii $r_x$ and $r_y$ [see Eq. (23)]. Uniform, rectangular transverse spatial grids are employed with $x$- and $y$-grid increments $\Delta x$ and $\Delta y$ ($\Delta x = \Delta y$) chosen for

$$N_r = \sqrt{\frac{r_x r_y}{\Delta x \Delta y}}$$  \hspace{1cm} (1)$$

zones (typical $N_r \in [20, 200]$) across the matched beam radius, with $N_r$ sufficiently large to resolve the structure of the beam edge. Round (WARP, with $r_p$ radius) or square (B-DYN, with $2r_p$ side length) conducting beam pipes are placed on the grid far enough from the matched envelope excursions with

$$N_p = \frac{r_p}{\sqrt{r_x r_y}}$$  \hspace{1cm} (2)$$

chosen large enough (typical $N_p \simeq 3$ here) to render image-charge effects small. For a given value of $N_p$, image charge effects will be more strongly mitigated in WARP than B-DYN, because the round beam pipe more closely matches the equipotentials external to a roughly elliptical charge symmetry beam than a square pipe. In general, correct
image charge modeling requires implementing boundary conditions associated with the structure of the aperture under consideration in the field solver. The number of macro-particles per grid cell,

\[ N_{\text{pgg}} = \frac{N}{\pi r_x r_y / (\Delta_x \Delta_y)}, \]  

where \( N \) is the total number of particles loaded, is set large enough (typical \( N_{\text{pgg}} \in [10^2, 10^4] \) and even larger on parallel machines) to reduce statistical noise on the grid and to produce low noise in binned diagnostic quantities such as densities and kinetic temperatures. Generally, we find that the requirement of reducing noise for clear diagnostics to be more stringent than required for high-fidelity simulations. Symmetry factors are included in measuring \( N_{\text{pgg}} \) in WARP simulations. The axial particle advance stepsize \( \Delta_s \) is set for

\[ N_s = \frac{L_y}{\Delta_s} \]  

to resolve both rapidly varying in \( s \) applied-focusing forces of the lattice (more restrictive), and evolving collective space-charge waves (generally less restrictive). Total advance lengths in \( s \) are carried out over relatively small numbers of lattice periods because the purpose of the present analysis is to evaluate initial transient deviations from the load to stress non-equilibrium like characteristics rather than collective relaxations over longer evolutions[14, 48, 49]. Diagnostic plots of binned density are contrasted at successive lattice periods to emphasize changes. Spatial binning grids can be independently set from the fieldsolve grid to allow use of coarser diagnostic meshes that reduce noise while resolving relevant features.

The simulation parameters \( N_r \) and \( N_s \) should also set consistently with resolving the characteristic Debye screening length \( \lambda_D = \sqrt{\varepsilon_0 T / (q^2 n)} \) [see Secs. III and Appendix F]. Here, \( T \) and \( n \) are characteristic spatially-averaged kinetic temperature and density measures over the beam. One expects that the radial fall-off distance of the beam density will be related to the Debye length, and that resolving the edge (i.e., \( N_r \) sufficiently large) will result in the number of cells per Debye length,

\[ N_D = \frac{\lambda_D}{\sqrt{\Delta_x \Delta_y}}, \]  

being sufficiently large to resolve screening of interactions for high space-charge intensity. Likewise, controlling statistical noise (i.e., \( N_{\text{pgg}} \) sufficiently large) on a grid chosen to resolve the Debye length will generally assure that the number of particles within a characteristic Debye screening circle

\[ N_{\text{ppgD}} = N \frac{\lambda_D^2}{r_x r_y} \]  

is sufficiently large. For charged particle beams with nonuniform temperature and density as well as an effective edge radii \( r_x \) and \( r_y \) that evolve in the focusing lattice, issues of adequate resolution of plasma parameters can depend on the specific distribution and application. Although some guidance exists in simple neutral plasma systems[12, 13], generally for intense beams these issues must be explored carefully to establish confidence that quantities examined are adequately represented and numerically converged.

### III. FORMULATION AND REVIEW OF INITIAL TRANSVERSE KINETIC DISTRIBUTIONS COMMONLY EMPLOYED IN SIMULATIONS OF LINEAR-FOCUSING CHANNELS

We consider a beam of particles of charge \( q \) and rest mass \( m \). The beam can be fully specified by the \( \mathbf{x} \cdot \mathbf{p} \) phase-space coordinates of the particles evolving in time. For present purposes, we model an axially thin, transverse slice of beam evolving in the accelerator lattice as a function of the axial coordinate \( s \) of the slice in the machine. The slice moves axially with velocity \( \beta_{bc} = \text{const} \) and relativistic gamma factor \( \gamma_b = 1 / \sqrt{1 - \beta_{bc}^2} = \text{const} \). Here, \( c \) is the speed of light in vacuo. The transverse phase-space of the beam is described by the spatial coordinate \( \mathbf{x}_\perp = x \hat{x} + y \hat{y} \) and the angle \( \mathbf{x}_\perp' \) that the particle makes with the axis of the machine. Primed henceforth denote derivatives with respect to \( s \), and in the paraxial approximation, \( \mathbf{x}_\perp' \approx v_\perp / (\beta_{bc} c) \), where \( v_\perp \) is the transverse particle velocity. In the Vlasov description, the slice is modeled by a continuous, single-particle distribution function \( f_\perp(x_\perp, x_\perp', s) \). In the paraxial limit, \( f_\perp \) evolves as an incompressible fluid in 4D transverse phase-space according to the nonlinear Vlasov equation[30–32, 63, 64]

\[ \left\{ \frac{\partial}{\partial s} + \frac{\partial H_\perp}{\partial x_\perp'} \cdot \frac{\partial}{\partial x_\perp} - \frac{\partial H_\perp}{\partial x_\perp} \cdot \frac{\partial}{\partial x_\perp'} \right\} f_\perp(x_\perp, x_\perp', s) = 0. \]  

(7)
Here,
\[ H_{\perp}(x_\perp, x'_\perp) = \frac{1}{2} x'^2_\perp + \frac{1}{2} \kappa x^2 + \frac{1}{2} \kappa y^2 + \frac{q}{m \gamma_0^2 \gamma_0^2} \langle \ldots \rangle \phi \tag{8} \]
is the single-particle Hamiltonian, \( \kappa_j(s) \) \((j = x, y)\) are the usual functions describing linear applied-focusing forces of the lattice[31, 74], and \( \phi(x_\perp, s) \) is the self-field potential generated by the beam space-charge. The potential \( \phi \) satisfies the transverse Poisson equation
\[ \nabla^2 \phi = -\frac{q}{\varepsilon_0} \int d^2 x'_\perp f_{\perp}, \tag{9} \]
with \( \phi \) subject to the appropriate boundary conditions on the transverse machine aperture. Here, \( \varepsilon_0 \) is the permittivity of free-space.

The Vlasov-Poisson system given by Eqs. (8)–(9) model the transverse beam evolution in the continuum approximation. The system is solved as an initial value problem where \( f_{\perp}(x_\perp, x'_\perp, s) \) is specified at some initial value of \( s = s_i \). Any positive-definite distribution function formed from a set of single-particle constants of the motion \( \{C_i\} \) will produce a valid, exact “equilibrium” solution to the Vlasov equation. Self-consistency requires that \( f_{\perp}(\{C_i\}) \) generates the required self-field configuration needed for validity of the constants of the motion. Self-consistency is highly nontrivial for focusing channels with \( \kappa_j \) varying applied-focusing forces described by \( \kappa_j(s) \). Only the KV distribution (see Sec. III A) is a known exact self-consistent Vlasov equilibrium for \( s \)-varying \( \kappa_j(s) \). In contrast, for continuous-focusing with \( \kappa_j = \text{const} \) (see Sec. III B), \( H_{\perp} \) is a valid constant of the motion and an infinite variety of equilibrium distributions are readily constructed.

In direct Vlasov simulations, a specified initial \((s = s_i)\) distribution \( f_{\perp}(x_\perp, x'_\perp, s = s_i) \) need only be loaded on the phase-space grid of the simulation. For distributions without singularities or sharp edges the distribution loading for direct Vlasov codes is straightforward. The spatial \( x_\perp \) and angle \( x'_\perp \) grid of the simulation should, of course, be chosen accordingly to resolve distribution variations in phase-space. For beams with sharp edges or discontinuities, there will generally be significant errors involved in discretizing the distribution unless numerical methods that are specific to the type of distribution are employed. For more common PIC simulations[12], a correct distribution of macro-particles must be synthesized to represent the initial distribution. Although the PIC method can simplify the treatment of distributions with sharp edges or discontinuities, sufficiently large numbers of macro-particles must be employed to adequately sample the distribution and limit statistical noise associated with the discretized representation. Care must be taken to prevent undesired correlations between particles. Generally procedures are formulated to load phase-space coordinates exploiting distribution symmetries and using probability transforms of pseudo-random uniform deviates commonly available in mathematical library functions. This is generally preferable to Monte-Carlo sampling of \( f_{\perp} \) due to statistical noise issues. Examples of explicit macro-particle initialization methods for various distributions will be discussed in subsequent sections.

Equations relating the focusing functions \( \kappa_j \) to magnetic and/or electric fields of practical focusing elements are presented in Ref. [31, 74]. If the lattice has nonlinear applied-fields, appropriate terms can be added the Vlasov equation (7) and the \( \kappa_j \) functions describe only the linear component focusing terms (excluding skew couplings). The \( \kappa_j \) can be periodic in \( s \) or not. For periodic lattices, the scale of the \( \kappa_j \) can be regarded as fixed by the undepressed phase-advances \( \sigma_{0j} \) (measured in degrees per lattice period) of a single-particle evolving in the absence of the beam in the linear applied-fields of the lattice[31, 74]. For the FODO quadrupole lattice used in illustrative simulations in this paper, \( \sigma_{0x} = \sigma_{0y} = \sigma_0 \).

The beam line-charge density,
\[ \lambda = q \int d^2 x_{\perp} \int d^2 x'_{\perp} f_{\perp} \tag{10} \]
is constant \((\lambda = \text{const})\) in slice models when particles are not lost from the system. In later 3D generalizations \( \lambda \) will be allowed to vary with \( s \) in a specified manner. Statistical averages over the full transverse phase-space of the beam slice are denoted by
\[ \langle \ldots \rangle_{\perp} = \frac{\int d^2 x_{\perp} \int d^2 x'_{\perp} \cdots f_{\perp}}{\int d^2 x_{\perp} \int d^2 x'_{\perp} f_{\perp}}, \tag{11} \]
and restricted angle averages over \( x_{\perp} \) by
\[ \langle \ldots \rangle_{x_{\perp}} = \frac{\int d^2 x'_{\perp} \cdots f_{\perp}}{\int d^2 x'_{\perp} f_{\perp}}. \tag{12} \]
We will frequently employ distribution moments such as the number density of beam particles

\[ n = \int d^2 x'_\perp f'_\perp, \tag{13} \]

the \(x\)- and \(y\)-plane coherent flow angles \(\langle x'\rangle_{x'_\perp}\) and \(\langle y'\rangle_{y'_\perp}\), and the incoherent flows (i.e., effective kinetic temperatures)

\[ T_x \equiv \langle (x' - \langle x'\rangle_{x'_\perp})^2 \rangle_{x'_\perp} = \langle x'^2_{x'_\perp} - \langle x'\rangle^2_{x'_\perp}, \tag{14} \]

with an analogous equation for \(T_y\). Moments that are formed by integrating over degrees of freedom of the distribution \(f'_\perp\) are sometimes called projections (e.g., the density \(n\) is the \(x-y\) distribution projection). Generally, to account for centroid motion, transverse phase-space coordinates are measured relative to the charge center of mass of the beam using

\[ \tilde{x}_\perp = x_\perp - \langle x_\perp \rangle_\perp, \]

\[ \tilde{x}'_\perp = x'_\perp - \langle x'_\perp \rangle_\perp. \tag{15} \]

For notational simplicity, we henceforth assume an on-axis centroid with \(\langle x_\perp \rangle_\perp = 0 = \langle x'_\perp \rangle_\perp\). It is straightforward to modify results presented for nonzero centroid evolution by replacing \(x_\perp \rightarrow \tilde{x}_\perp\).

If the beam slice is accelerated axially by specified longitudinal forces, then \(\gamma_0/b_0 \neq \text{const}\) is allowed to vary as some prescribed function of \(s\). It is shown in Appendix A that if the acceleration is slowly varying, then the formulation presented above is applicable when interpreted in terms of appropriately transformed variables. Consequently, results presented for \(\gamma_0/b_0 = \text{const}\) here and in subsequent sections can also be applied to accelerating beams provided that variables are consistently interpreted. This remains true even if the beam is axially long and \(\gamma_0/b_0\) varies from the head to the tail of the pulse.

A. The KV equilibrium distribution

The so-called KV equilibrium distribution was constructed by Kapchinskij-Vladimirskij[36] and has been extensively studied[30–32, 37–45, 63, 64]. Here, we review properties of the distribution for later use in formulating alternative, smooth distributions to load. The KV distribution can be symmetrically expressed as

\[ f_\perp(x_\perp, x'_\perp, s) = \frac{\lambda}{q^n \varepsilon x \varepsilon y} \delta \left[ \frac{x}{r_x} \right]^2 + \left( \frac{r_x x' - r_x x}{\varepsilon_x} \right)^2 + \left( \frac{y}{r_y} \right)^2 + \left( \frac{r_y y' - r_y y}{\varepsilon_y} \right)^2 - 1 \]. \tag{16} \]

Here, \(\delta(x)\) is the usual Dirac delta-function \(\delta(x) = 0\) for \(x \neq 0\) and \(\int dx \, f(x) \delta(x) = f(0)\) for any integrable function \(f(x)\), \(r_j = r_j(s)\) \((j = x, y)\) are the edge (envelope) radii of the uniform-density elliptical beam core, \(r'_j = r'_j(s)\) are the envelope angles, and \(\varepsilon_j = \text{const}\) are the rms-edge emittances of the beam. The KV distribution is an exact equilibrium solution of the Vlasov equation (7) in the absence of nonlinear image-charge forces (axisymmetric system with \(\partial/\partial \theta = 0\), or free-space approximation)[30, 32, 36]. This follows because the KV distribution is a function of single-particle Courant-Snyder invariants of the linear applied-focusing and linear space-charge defocusing forces generated by the distribution itself (see Appendix B). Using techniques similar to those employed in the derivation of the density inversion theorem in continuous focusing channels (see Sec. III B), it can be shown that the delta-function form of Eq. (16) arises naturally to consistently produce a uniform density elliptical beam consistent Courant-Snyder invariant forms[63]. Canonical transforms can also be applied to equivalently express a wide variety superficially different appearing expressions of the KV distribution in symmetrical canonical form [i.e., \(f(q,p) \propto \delta(q^2 + p^2 - 1)\) for 2D canonical variables \(q\) and \(p\)][45].

Projections and moments of the KV distribution are most readily calculated using canonical transforms (see Appendix C and Ref. [30, 63]). All two-dimensional (2D) phase-space projections of the KV distribution correspond to uniformly-filled ellipses. The orientation and shape of the elliptical projections evolve in \(s\) as the beam propagates in the lattice. The density \(n\) of the KV distribution (i.e., the \(x-y\) projection) is uniform within an elliptical beam envelope with

\[ n = \int d^2 x' \, f'_\perp = \begin{cases} \frac{\lambda}{q \pi^2 r_x r_y}, & \text{if } \left( \frac{x}{r_x} \right)^2 + \left( \frac{y}{r_y} \right)^2 < 1, \\ 0, & \text{otherwise.} \end{cases} \tag{17} \]
This uniform-density beam produces linear self-field forces within the beam when nonlinear image-charge effects are absent (free-space or aperture sufficiently large). Two-dimensional $x$-$x'$ and $y$-$y'$ phase-space projections can be calculated as

$$\int dy \int dy' f_\perp = \begin{cases} \frac{\lambda}{\eta x^2 s}, & \text{if } \left( \frac{x}{\tau_x} \right)^2 + \left( \frac{r_x x' - r_y}{\tau_x} \right)^2 < 1, \\
0, & \text{otherwise,} \end{cases}$$

$$\int dx \int dx' f_\perp = \begin{cases} \frac{\lambda}{\eta y^2 s}, & \text{if } \left( \frac{y}{\tau_y} \right)^2 + \left( \frac{r_y y' - r_x}{\tau_y} \right)^2 < 1, \\
0, & \text{otherwise.} \end{cases}$$

Various moments of the KV distribution are summarized in Table I. From these moments, the $j$-plane coherent flow angles are

$$\langle x' \rangle_\perp = \begin{cases} r_x' \frac{r_x}{\tau_x}, & \text{if } \left( \frac{x}{\tau_x} \right)^2 + \left( \frac{y}{\tau_y} \right)^2 < 1, \\
0, & \text{otherwise,} \end{cases}$$

$$\langle y' \rangle_\perp = \begin{cases} r_y' \frac{r_y}{\tau_y}, & \text{if } \left( \frac{x}{\tau_x} \right)^2 + \left( \frac{y}{\tau_y} \right)^2 < 1, \\
0, & \text{otherwise,} \end{cases}$$

and the kinetic temperatures [i.e., incoherent flows, see Eq. (14)] are,

$$T_j = \begin{cases} \frac{e^2}{2r_j^2} \left( 1 - \frac{e^2}{r_x^2} - \frac{e^2}{r_y^2} \right), & \text{if } \left( \frac{x}{\tau_x} \right)^2 + \left( \frac{y}{\tau_y} \right)^2 < 1, \\
0, & \text{otherwise.} \end{cases}$$

These parabolic temperature profiles drop to zero at the beam edge, which is consistent with linear thermal pressure and a sharp beam edge.

Although the full four-dimensional KV distribution (16) is a manifest (hypershell) invariant, projections of the beam evolve in $s$. In the absence of perturbations (applied-field, perturbed distribution, induced image-charges, etc.), the envelope radii $r_j$ evolve according to the so-called KV envelope equations\[31, 36, 74\]

$$r_j'' + \kappa_j r_j - \frac{2Q}{r_x + r_y} - \frac{e_j^2}{r_j^2} = 0.$$  \quad (21)

Here,

$$Q = \frac{q\lambda}{2\pi\epsilon_0 m c^2 \gamma_0^3 \beta^2_0} = \text{const},$$  \quad (22)

is the dimensionless perveance. If the focusing functions $\kappa_j$ are periodic in $s$, and the initial beam parameters are “matched”, then the solution for $r_j$ will have the same periodicity as the lattice. This, in general, requires specific choices for the envelope functions $r_j$ and angles $r_j'$ at the axial coordinate $s$ where the distribution is specified\[31, 74\]. An efficient procedure for numerically calculating the matched beam envelope under various parameter specifications is presented in Ref. [75].

For the KV distribution, the envelope radii $r_j$, the envelope angles $r_j'$, and the emittances $\varepsilon_j = \text{const}$ are related to second order statistical moments of the distribution (see also Table I) as

$$r_x = 2\langle x^2 \rangle_\perp^{1/2}, \quad r_y = 2\langle y^2 \rangle_\perp^{1/2},$$

$$r_x' = 2\langle xx' \rangle_\perp^{1/2}, \quad r_y' = 2\langle yy' \rangle_\perp^{1/2}.$$  \quad (23)

and

$$\varepsilon_x = 4\langle x^2 \rangle_\perp \langle x^2 \rangle_\perp - \langle xx' \rangle_\perp^2 \rangle_\perp^{1/2}, \quad \varepsilon_y = 4\langle x^2 \rangle_\perp \langle x^2 \rangle_\perp - \langle xx' \rangle_\perp^2 \rangle_\perp^{1/2}. \quad (24)$$

When the envelope $r_j$ is matched to a periodic focusing lattice, the depressed phase-advance of particles oscillating within the core of the beam under the action of linear applied-focusing fields and linear space-charge defocusing fields can be calculated from\[30, 31, 74\]

$$\sigma_j = \varepsilon_j \int_0^{L_p} \frac{ds}{r_j^2},$$  \quad (25)
TABLE I: Moments of the KV distribution. All second-order moments not listed vanish (i.e., $\int d^2x_\perp xyf_\perp = 0$, $\langle xy\rangle_\perp = 0$).

where $L_p$ is the lattice periodicity length. The ratio of depressed to undepressed phase-advance $\sigma_j/\sigma_{0j}$, also called the tune depression, provides a convenient measure of relative space-charge strength with $\sigma_j/\sigma_{0j} \to 1$ in the limit of vanishingly small space-charge strength ($Q = 0$), and $\sigma_j/\sigma_{0j} \to 0$ in the limit of maximum space-charge strength ($\varepsilon_j = 0$). For systems with symmetry between the $x$- and $y$-planes that result in $\sigma_x = \sigma_y$, we denote $\sigma_j \equiv \sigma$ for notational simplicity.

Although Eqs. (23)–(25) apply to a KV beam, they are often used to characterize non-KV distributions in an “rms-equivalent” sense[31, 76], where a non-KV distribution (with generally nonlinear beam self-fields internal to the beam) is replaced by a KV distribution with the same energy, line-charge, and first- and second-order moments as “rms-equivalent” sense[31, 76], where a non-KV distribution (with generally nonlinear beam self-fields internal to the beam) is replaced by a KV distribution with the same energy, line-charge, and first- and second-order moments as.

The KV envelope equation (21) can be employed with self-consistent $s$-varying emittances [defined by Eq. (24)] as an average force balance equation for statistical edge radii $r_j$ [defined by Eq. (23)] that describe a wide variety of distributions[31, 74, 76]. If the emittance variations have a negligible effect on the the evolution of the $r_j$, then the KV equation can be applied with $\varepsilon_j = \text{const}$ for low-order system modeling. Bands of parametric instability described by the KV envelope equations predict parameter regions where machines cannot reliably operate[31, 74, 79]. Unfortunately, the singular structure of the KV distribution leads to unphysical, higher-order collective mode instabilities[31, 32, 37–44] that render the distribution generally unsuitable to employ as an initial distribution function in Vlasov simulations of beams with high space-charge intensity. Further reducing the applicability of the KV distribution, M. Neuman has shown that the transverse 2D KV distribution is not generalizable to 3D (see Appendix A of Ref. [45]). This follows from bounds established by Neuman which show that the density projection of any distribution of 3D linear-force Courant-Snyder invariants cannot produce a uniform density projection in 3D necessary for self-consistency.

Loading the initial KV distribution (16) in a direct Vlasov code can be problematic due to the singular (delta-function) structure of $f_\perp$. Optimal loading procedures generally center on how to best represent the singular delta-function defining the hyper-shell surface in 4D phase-space where $f_\perp = \text{const}$ on the discrete phase-space grid of the
simulation. For PIC simulations, an initial KV distribution can be loaded several ways. In one approach, the fact that the Courant-Snyder invariant argument of the delta-function define a hyper-ellipsoidal shell in 4D phase-space with

\[
\left( \frac{x}{r_x} \right)^2 + \left( \frac{r_xx' - r_x'x}{\epsilon_x} \right)^2 + \left( \frac{y}{r_y} \right)^2 + \left( \frac{r_yy' - r_y'y}{\epsilon_y} \right)^2 = 1
\]

(26)
can be employed. A finite number of particles can be loaded with phase-space coordinates uniformly distributed on the 4D hyper-ellipsoid (or to the extent possible with a finite number of particles) defined by Eq. (26).

In another particle loading approach, the KV distribution property that \( \int dx_1 \int dx_2 f_\bot \) is a uniformly-filled ellipse when \( x_1 \) and \( x_2 \) are chosen to be any two of the phase-space coordinates \( x, y, x', y' \) can be exploited. This approach has the virtue that techniques developed can be generalized to apply to loading other classes of distributions (see Secs. IIIIB and IV). One procedure[80] based on uniform elliptical projections is to first load particle coordinates \( \mathbf{x}_\bot \) consistent with uniform beam density within the elliptical envelope radii \( r_j \) [see Eq. (17)]. This can be accomplished using two independent, uniformly-distributed random numbers \( \hat{u}_r \in [0,1) \) and \( \hat{u}_\theta \in [0,1) \) and taking

\[
x = r_x \sqrt{\hat{u}_r} \cos(2\pi \hat{u}_\theta), \quad y = r_y \sqrt{\hat{u}_r} \sin(2\pi \hat{u}_\theta).
\]

(27)

Equation (27) is readily derived by transforming a uniformly-filled unit disk to a uniformly-filled ellipse with major radii \( r_j \). With spatial coordinates set according to Eq. (27), particle angles \( \mathbf{x}'_\bot \) can be resolved into coherent and incoherent components as

\[
\mathbf{x}'_\bot = \mathbf{x}'_\bot |_c + \mathbf{x}'_\bot |_i,
\]

(28)

with the coherent (i.e., generally \( \langle \mathbf{x}'_\bot |_c \rangle_{\mathbf{x}_\bot} \neq 0 \)) components set consistently with Eq. (19) as

\[
x'|_c = r_j x'/r_x, \quad y'|_c = r_j y'/r_y,
\]

(29)

and the the incoherent (i.e., \( \langle \mathbf{x}'_\bot |_i \rangle_{\mathbf{x}_\bot} = 0 \)) components constrained [see Eq. (26)] to satisfy

\[
\left( \frac{r_xx'|_c}{\epsilon_x} \right)^2 + \left( \frac{r_yy'|_c}{\epsilon_y} \right)^2 = 1 - \frac{x'^2}{r_x^2} - \frac{y'^2}{r_y^2}.
\]

(30)

Incoherent angles can be generated consistent with this constraint without introducing correlations by using another independent, uniformly-distributed random number \( \hat{u}_\varphi \in [0,1) \) and taking

\[
x'|_i = \frac{\epsilon_x}{r_x} \sqrt{1 - \frac{x'^2}{r_x^2} - \frac{y'^2}{r_y^2} \cos(2\pi \hat{u}_\varphi)}, \quad y'|_i = \frac{\epsilon_y}{r_y} \sqrt{1 - \frac{x'^2}{r_x^2} - \frac{y'^2}{r_y^2} \cos(2\pi \hat{u}_\varphi)}.
\]

(31)

The finite number of PIC macro-particles loaded can never exactly represent the distribution. There will always be statistical errors resulting from finite statistics and the shape of the macro-particles employed. Also, the discrete spatial grid employed in the PIC method will generally introduce errors in resolving the sharp edge of the KV distribution. For cases where the KV distribution is unstable, these statistical and gridding errors will generally project on unstable collective modes complicating applications of the KV distribution.[31, 37, 39].

Statistical noise associated with loads in PIC simulations can be substantially reduced by replacing the pseudo-random numbers \( \hat{u}_r, \hat{u}_\theta, \) and \( \hat{u}_\varphi \) with ordered sets of numbers (based on digit-reversed numbers, Fibonacci numbers, etc.) in the interval \([0,1)\) to obtain more uniform particle spacing in phase-space[21]. Such techniques are especially useful for high-resolution tests of equilibrium loads. However, as simulations are advanced in \( s \), noise will eventually grow to levels consistent with the underlying statistics and discretizations associated with the numerical methods employed. Considerable care should be taken when using ordered numbers to load both particle coordinates \( \mathbf{x}_\bot \) and angles \( \mathbf{x}'_\bot \) that unphysical phase-space correlations are not introduced via the systematic orderings. The possibility of introducing unwanted correlations can be mitigated (at the expense of more load noise) by using ordered numbers only in the particle coordinate or angle loads, but not both. Comments given here on the application of ordered sets of numbers in generating loads are also applicable to loads developed in subsequent sections.

Numerous examples of KV beam Vlasov simulations can be found in the literature[31, 37, 39, 41, 62] and will not be repeated here. Intrinsic instabilities of the distribution are generally seeded by noise and errors specific to the loading method and numerical approximations employed. This renders results difficult to interpret, particularly for strong relative space-charge strength.
B. Continuous-focusing equilibrium distributions

The continuous-focusing model has been extensively studied by Davidson [30, 32], Reiser [31], and broad reviews can be found in U.S. Particle Accelerator School courses [64]. Here we parallel a formulation presented in U.S. Particle Accelerator School lectures [63] to review general properties of the continuous-focusing model for later application in formulating approximate Vlasov loads for focusing channels with $s$-varying applied-focusing forces that improve on the KV model. Details of specific choices of continuous-focusing beam equilibria are presented in Appendix D–F. In a continuous-focusing channel, $\kappa_x = \kappa_y = k_{30}^2 = \text{const}$ and the transverse particle Hamiltonian $H_\perp$ given by Eq. (8) is a single-particle constant of the motion with $H_\perp = \text{const}$. Therefore, any function

$$f_\perp(x_\perp, x_\perp', s) = f_\perp(H_\perp)$$  \hspace{1cm} (32)

satisfying $f_\perp \geq 0$ at $s = s_i$ will form a valid stationary continuous-focusing equilibrium solution to the Vlasov equation (7). Moreover, functional bounds can be employed to show that the monotonicity condition $\partial f_\perp(H_\perp)/\partial H_\perp \leq 0$ is a sufficient condition for stability of the continuous-focusing equilibrium $f_\perp$ to both small- and large-amplitude perturbations [30, 32, 81–83]. Conversely, any continuous-focusing equilibrium not satisfying $\partial f_\perp(H_\perp)/\partial H_\perp \leq 0$ meets a necessary condition for instability and intuitively one expects that such non-monotonic profiles to have “free energy” to drive instabilities.

It can be shown [84] that any valid choice of function $f_\perp(H_\perp)$ with $\partial f_\perp(H_\perp)/\partial H_\perp \leq 0$ necessarily produces an axisymmetric ($\partial/\partial \theta = 0$) continuous-focusing equilibrium when the aperture is axisymmetric or sufficiently large to have a negligible effect on the beam (as will be assumed to hold in the remainder of this section). In this case, the Poisson equation (9) can be expressed as

$$-\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial \phi}{\partial r} \right) = -\frac{q_m}{\epsilon_0} \int d^2x_\perp \frac{f_\perp(H_\perp)}{\epsilon_0},$$ \hspace{1cm} (33)

where $r = \sqrt{x^2 + y^2}$ is the transverse radial coordinate. It is convenient to define an effective potential [30–32, 85]

$$\psi(r) \equiv \frac{1}{2} k_{30}^2 r^2 + \frac{q \phi(r)}{m c^2 \gamma^2}.$$ \hspace{1cm} (34)

Then,

$$H_\perp = \frac{1}{2} x_\perp^2 + \psi$$ \hspace{1cm} (35)

and system axisymmetry can be exploited to calculate the beam density as

$$n(r) = \int d^2x_\perp f_\perp(H_\perp) = 2\pi \int_\psi^\infty \frac{dH_\perp f_\perp(H_\perp)}{dH_\perp},$$ \hspace{1cm} (36)

to recast the Poisson equation (33) as

$$-\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial \psi}{\partial r} \right) = 2k_{30}^2 - \frac{2\pi q^2}{m c^2 \gamma^2} \int_\psi^\infty \frac{dH_\perp f_\perp(H_\perp)}{dH_\perp}.$$ \hspace{1cm} (37)

Explicit solution of this equation for $\psi$ [or equivalently Eq. (33) for $\phi$] is necessary to calculate the continuous-focusing equilibrium density profile $n = \int d^2x_\perp f_\perp(H_\perp)$. For most physically appealing, smooth choices of $f_\perp(H_\perp)$ the equation is highly nonlinear and the solution must be done numerically. Details on how the solution is best carried out vary with the choice of $f_\perp(H_\perp)$. In some cases it can be advantageous to eliminate $\psi$ in Eq. (37) in terms of the density $n$ using Eq. (36).

To better understand the continuous-focusing equilibrium structure, it can be useful to calculate the radial kinetic temperature profile $T_x = \langle x^2 \rangle_x$ [see Eq. (14)] of the axisymmetric equilibrium defined by $f_\perp(H_\perp)$. By symmetry, $T_x = T_y$. Using Eq. (35), explicit calculation of $T_x(r)$ can be simplified as

$$T_x(r) n(r) = \frac{1}{2} \int d^2x_\perp x_\perp^2 f_\perp(H_\perp) = 2\pi \int_\psi^\infty \frac{dH_\perp f_\perp(H_\perp)}{dH_\perp} (H_\perp - \psi) f_\perp(H_\perp).$$ \hspace{1cm} (38)

The axisymmetric continuous-focusing equilibrium beam formed by $f_\perp(H_\perp)$ will be envelope matched to the continuous-focusing channel with $r_j \equiv r_b = \sqrt{2(r^2)_\perp}$ = const satisfying the rms-envelope equation

$$k_{30}^2 r_b^2 - \frac{Q}{r_b} - \frac{\epsilon^2}{r_b^2} = 0.$$ \hspace{1cm} (39)
Here, $f_\perp(H_\perp)$ can be employed to consistently calculate the statistical beam envelope radius $r_b$ [see Eq. (23)] as

$$r_b^2 = 2(r^2)_\perp = \int_0^\infty dr \int_0^\infty dH_\perp f_\perp(H_\perp).$$

(40)

the line-charge density $\lambda = \text{const}$ [see Eq. (10)], or perveance $Q = q\lambda/(2\pi\epsilon_0mc^2\gamma_0^3\beta_b^2)$ [see Eq. (22)] as,

$$\lambda = (2\pi)^2 q \int_0^\infty dr \int_0^\infty dH_\perp f_\perp(H_\perp).$$

(41)

and the rms-edge emittance $\varepsilon_j \equiv \varepsilon_b = \text{const}$ [see Eq. (24)] as

$$\varepsilon_b^2 = 2r_b^2(x_b^2)_\perp = 2r_b^2 \int_0^\infty dr \int_0^\infty dH_\perp (H_\perp - \psi)f_\perp(H_\perp).$$

(42)

Comparing Eqs. (38) and (42) and employing previous results, note that the beam emittance $\varepsilon_b$ is related to the spatially averaged radial temperature profile of the beam by

$$\varepsilon_b^2 = 2r_b^2 \int_0^\infty dr \int_0^\infty dH_\perp \frac{\varepsilon_b^2}{\psi}.$$
Using \( \lambda = q \tilde{n} \pi r_b^2 \) with \( \tilde{n} = \text{const} \) the density within the beam, Eq. \( \text{(46)} \) can be written as \( f_\perp = \frac{\omega_p^2}{2 \pi} \delta(H_\perp - H_b) \). This alternative expression for the KV distribution function in a continuous-focusing channel is commonly employed in the literature\([30-32, 63]\). The equivalence of Eqs. \( \text{(16)} \) and \( \text{(46)} \) shows that for continuous-focusing, the Courant-Snyder invariant form of the KV distribution reduces to the expected Hamiltonian invariant form. This should not be interpreted as implying that the Courant-Snyder invariant is equivalent to \( H_\perp = \text{const} \) for other than continuous-focusing. In periodic-focusing channels the Hamiltonian \( H_\perp \) has explicit \( s \) dependence from the applied-focusing terms. Unfortunately, this \( s \) dependence renders \( H_\perp \) inappropriate for constructing single-particle invariants and equilibrium distribution functions for focusing channels with \( s \)-varying focusing forces. It is also interesting to point out that \( \partial f_\perp(H_\perp)/\partial H_\perp \) changes sign about \( H_\perp = H_b \), showing that the KV distribution does not satisfy the sufficient condition for stability and therefore satisfies a necessary condition for instability. Well-known kinetic analyses show that the continuous-focusing KV distribution is unstable for all space-charge strengths satisfying \( \sigma/\sigma_0 < 0.3985\)\([37, 38]\).

The KV model can be applied in an rms-equivalent beam sense to characterize relative space-charge strength of a continuous-focusing equilibrium with nonuniform \( n(r) \). Taking the equivalent axial “lattice period” length of phase accumulation to be \( L_p \), we first set \( k_{30} = \sigma_0/L_p \), where \( \sigma_0 \) is the undepressed particle phase-advance over \( L_p \). Then the depressed phase-advance equation \( \text{(25)} \) for \( \sigma_j \equiv \sigma \) is applied over an axial length \( L_p \) with \( \varepsilon_j = \varepsilon_b \) and \( r_j = r_b \) given by the matched beam envelope equation \( \text{(39)} \). This yields

\[
\frac{\sigma}{\sigma_0} = \sqrt{1 - \frac{Q}{k_{30}^2 \varepsilon_b^2}} = \frac{\varepsilon_b}{k_{30} \sigma_0}.
\]

(47)

In this context, \( \sigma/\sigma_0 \) characterizes the relative space-charge strength of an equilibrium with \( \sigma/\sigma_0 = 1 \) \( (Q = 0) \) corresponding to negligible space-charge strength, and \( \sigma/\sigma_0 = 0 \) \( (\varepsilon_b = 0) \) corresponding to an equilibrium with maximum space-charge strength.

Some authors employ alternative dimensionless parameters to \( \sigma/\sigma_0 \) when characterizing relative space-charge strength. One common choice\([32]\) is to define a normalized self-field intensity parameter \( s_b \) as the ratio of one-half of the squared relativistic plasma frequency formed from the on-axis \( (r = 0) \) density \( \tilde{n} = n(r = 0) \) of the distribution \( \{ \omega_p^2/2 \tilde{n} \} \) with \( \omega_p^2 = q^2 n/(me_0) \) to the squared frequency of single-particle oscillations in the applied-focusing field \( \{ \tilde{n}_b^2 \beta_b^4 c^2 k_{30} \} \), i.e.,

\[
s_b \equiv \frac{\omega_p^2}{2 \gamma_b^4 \beta_b^4 c^2 k_{30}^2}.
\]

(48)

For a KV continuously-focused beam, \( s_b \) and \( \sigma/\sigma_0 \) are simply related by

\[
s_b = 1 - \left( \frac{\sigma}{\sigma_0} \right)^2.
\]

(49)

The dimensionless self-field parameter \( s_b \) defined in terms of the on-axis density of the beam can be algebraically convenient when specifying continuous-focusing equilibria with monotonic radial density profiles \( n(r) \) satisfying \( \partial n(r)/\partial r \leq 0 \). However, monotonic equilibrium specifications of \( f_\perp(H_\perp) \) with \( \partial f_\perp(H_\perp)/\partial H_\perp \leq 0 \) (see examples in Appendices D-F) generally result in \( s_b \approx 1 \) over a relatively large range of high space-charge intensity (with rms-equivalent \( \sigma/\sigma_0 \approx 1/2 \)), rendering \( s_b \) a relatively insensitive measure in regimes where \( s_b \to 1 \).

The form of an continuous-focusing equilibrium distribution \( f_\perp(H_\perp) \) and the corresponding density \( n(r) \) are strongly linked. For monotonic density profiles with \( \partial n(r)/\partial r \leq 0, \tilde{n} = n(r = 0) \) is maximum value of \( n(r) \) and the density inversion theorem\([30, 32, 63, 86]\) can be employed to calculate the equilibrium function \( f_\perp(H_\perp) \) from a specified density profile as

\[
f_\perp(H_\perp) = -\frac{1}{2 \pi} \left. \frac{\partial n}{\partial \psi} \right|_{\psi = H_\perp}.
\]

(50)

If \( f_\perp(H_\perp) \) satisfies \( \partial f_\perp(H_\perp)/\partial H_\perp \leq 0 \), then the equilibrium specified by \( n(r) \) will be stable.

Although the structure of the continuous-focusing equilibria satisfying \( \partial f_\perp(H_\perp)/\partial H_\perp \leq 0 \) are physically appealing and stable, unfortunately, the continuous-focusing model cannot provide a general guide for properties of beam transport in realistic \( s \)-varying applied-focusing channels. The continuous focusing function \( \kappa_j = k_{30}^2 = \text{const} \) is equivalent to a partially neutralizing, immobile background charge density with \( \rho = -2m_e \gamma_b \beta_b^2 c^2 k_{30}^2/q = \text{const} \) and can only represent realistic, \( s \)-varying focusing forces in an average sense. Although this approximate correspondence can be useful in simplified estimates of transport properties where the system is far from instability, periodic-focusing...
channels have well known instabilities that are not present in the continuous-focusing limit\cite{15, 33–35}. Continuous-focusing analogies to periodic-focusing systems are typically found to become progressively worse as the strength of the applied-focusing field (as measured by \(\sigma_f\)) increases — particularly for alternating-gradient focusing. The desire for radially compact beams generally drives applications with high focusing strength, exacerbating this breakdown of approximate analogies.

To load the the continuous-focusing distributions (32) in direct Vlasov or PIC simulations, parameters used in defining the function \(f_\perp(H_\perp)\) should be determined in terms of usual beam parameters (i.e., \(k_{\perp i}, Q, \varepsilon_b, \text{etc.} \)). Such procedures are generally nontrivial, as evident from the examples in Appendices D–F. With equilibrium parameters specified, the effective potential \(\psi\) must then be calculated (generally numerically) within the beam to determine \(H_\perp = \frac{x_\perp^2}{2} + \psi\) and thereby fully specify \(f_\perp(H_\perp)\). For direct Vlasov simulations \(f_\perp(x_\perp^2/2 + \psi)\) can then be loaded on the 4D (or 3D/2D if axisymmetry is partially/fully taken into account) phase-space grid of the simulation.

For PIC simulations, macro-particles can be loaded to approximate the continuous-focusing distributions by building on techniques discussed in Sec. III A for initializing particles to model the KV distribution. First, the radial beam density profile \(n(r)\) can be calculated from Eq. (36) using the calculated radial effective potential \(\psi(r)\). Then macro-particle spatial coordinates \(x_\perp\) can be loaded consistent with this density profile using a probability transform to map particles distributed uniformly within a unit circle to a distribution consistent with the radial density profile \(n(r)\). This can be accomplished using independent, uniformly-distributed random numbers \(\hat{u}_r \in [0, 1)\) and \(\hat{u}_\theta \in [0, 1)\), carrying out a probability transformation\cite{12}

\[
\begin{align*}
\frac{\int_0^r \int_0^\infty d\tilde{r} \tilde{n}(\tilde{r})}{\int_0^\infty \int_0^\infty dr \tilde{n}(r)} &= \hat{u}_r, \\
\end{align*}
\]

and taking

\[
\begin{align*}
x &= r(\hat{u}_r) \cos(2\pi \hat{u}_\theta), & y &= r(\hat{u}_r) \sin(2\pi \hat{u}_\theta).
\end{align*}
\]

Here, \(r(\hat{u}_r)\) is the smallest positive solution of Eq. (51), and \(\hat{u}_\theta\) generates a uniform distribution of azimuthal coordinate angles in the axisymmetric beam. If a lower-dimensional simulation is used (with “ring” particles) to more efficiently model the axisymmetric beam, then only particle radii \(r(\hat{u}_r)\) need be calculated. The solution \(r(\hat{u}_r)\) must, in general, be solved numerically for smooth \(n(r)\). When a large number of particles must be loaded, the transform in Eq. (51) can be calculated for gridded values of \(\hat{u}_r \in [0, 1)\) and the corresponding gridded values of \(r(\hat{u}_r)\) stored to allow efficient calculation of \(r(\hat{u}_r)\) for arbitrary values of \(\hat{u}_r \in [0, 1)\) by calculating the nearest grid indices and interpolating. For cases where \(n(r)\) does not have a sharp edge, the grid will generally need to be cutoff at a radius beyond which the density is negligible. If a uniform grid is employed the cutoff should not be chosen too large or the resolution in the core of the distribution will be degraded (see for example, the thermal equilibrium analysis in Appendices, F and G). Some simple classes of density profiles allow analytical solution. For example, if the density is uniform within radius \(r = r_c\), then Eq. (51) yields \(r(\hat{u}_r) = r_c \sqrt{\hat{u}_r}\) [compare this to Eq. (27)] with \(r_x = r_y = r_c\).

With the particle coordinates loaded and the radial dependence of \(\psi(r)\) thereby specified, the particle angles \(x_\perp\) can be generated consistently with \(f_\perp(H_\perp)\) using an analogous procedure to the one employed for the coordinate loading. Taking \(H_\perp = U + \psi\) with \(U = x_\perp^2/2\), the probability transform

\[
\begin{align*}
\frac{\int_0^U d\hat{U} \int_0^\infty dU f_\perp(U + \psi)}{\int_0^\infty dU f_\perp(U + \psi)} &= \hat{u}_\psi,
\end{align*}
\]

is solved for \(U(\hat{u}_\psi)\) and then angles are set consistent with beam axisymmetry using

\[
\begin{align*}
x' &= \sqrt{2U(\hat{u}_\psi)} \cos(2\pi \hat{u}_\varphi), & y' &= \sqrt{2U(\hat{u}_\psi)} \sin(2\pi \hat{u}_\varphi).
\end{align*}
\]

Here, \(\hat{u}_\psi\) and \(\hat{u}_\varphi\) are independent, uniformly distributed random numbers with \(\hat{u}_\psi \in [0, 1)\) and \(\hat{u}_\varphi \in [0, 1)\). In general, \(U(\hat{u}_\psi)\) must be calculated numerically. Analogous to the case for the particle coordinates discussed above, values of the transform in Eq. (53) can be pre-calculated on a grid and interpolation applied to efficiently load a large number of particles. In simulations where beam axisymmetry is fully exploited, only \(r'\) may be necessary to initialize particles. In this case, using \(r' = (x'x' + y'y')/r\) and Eqs. (52) and (54), it follows that \(r'\) can be loaded as

\[
r' = \sqrt{2U(\hat{u}_\psi)} \cos(2\pi \hat{u}_r),
\]

with \(\hat{u}_r \in [0, 1)\) a uniformly-distributed random number.

Analogous to the situation discussed for the KV distribution in Sec. III A, the random numbers employed to load the continuous-focusing distribution \{\(\hat{u}_r, \hat{u}_\theta\)\} and/or \{\(\hat{u}_\psi, \hat{u}_\varphi\)\} can be replaced by ordered sets of numbers to reduce initial statistical noise.
It is interesting to point out that the loading formalism outlined above can be applied for a specified, stable monotonic decreasing radial density profile \( n(r) \) without detailed knowledge of the corresponding equilibrium function \( f_\perp(H_\perp) \) that specifies the continuous-focusing distribution. First, particle coordinates \( \mathbf{x}_\perp \) consistent with \( n(r) \) can be calculated from Eqs. (51) and (54). The equilibrium potential \( \psi \) can then be calculated from Eqs. (36) and (37), and this result applied in the inversion theorem (50) to implicitly specify \( f(H_\perp) \) for use in Eqs. (53) and (54) to load the particle angles \( \mathbf{x}_\perp \).

Because the continuous-focusing distributions are exact Vlasov equilibria, any evolution in simulated distribution from the loaded beam results from numerical approximations in the procedure used to load the distribution and/or in the Vlasov simulations. This property, when employing accurate loads, can render the continuous-focusing distributions useful for checking the accuracy of simulations. Two dimensional PIC slice simulations illustrating this point are shown in Fig. 2 for a waterbag (step-function) choice of \( f(H_\perp) \). Properties of the waterbag equilibrium are analyzed in detail in Appendix D. Codes and parameter choices made in the simulations are described in Sec. II. Simulations illustrated were carried out of strong relative space-charge strength \( (\sigma/\sigma_0 = 0.2) \), so the equilibrium radial density profile is flat in the core of the beam. The waterbag equilibrium has a sharp edge in phase-space projections, which can aid visualization of small evolutions induced by numerical approximations. Both an accurate simulation and a less accurate simulation with poorer resolution and statistics are shown. Details of the waterbag equilibrium distribution are presented in Appendix D and the simulations and parameter choices are described in Sec. II. To precisely load the distribution in both the accurate and less accurate cases, the radial density transformation (51) is solved on a uniform mesh of 500 points and the angle transform (53) is solved exactly (see discussions in Appendix D). In the accurate simulation, ordered digit-reversed numbers are used to generate a load with reduced noise in phase-space, whereas the less accurate simulation uses pseudo-random numbers to generate the load resulting enhanced initial statistical noise relative to ordered numbers. Statistical beam envelope radii \( r_j \) and emittances \( \varepsilon_j \) are calculated using Eqs. (23) and (24) with centroid measures subtracted [see Eq. (15) and the related discussion]. Quantities associated with the \( x- \) and \( y \)-axes (in black and red, respectively) as calculated from the gridded charge-density in the simulation with no additional smoothing. The density is normalized by the rms average measure, \( \lambda/(q\pi r_x r_y) \), so values not equal to unity indicate deviations from an rms equivalent KV beam. Density profile plots are superimposed with the density of an rms-equivalent KV beam (in green, with unit density as normalized). The \( x-x' \) phase-space projections are generated by plotting macro-particle markers that are color coded based on the local phase-space density. All particles are shown in the projections of the less accurate simulation, whereas a method is employed in the plots of the accurate simulation that shows almost all particles in the low-density regions and a sampling of particles in the high-density regions.

The accurate simulation shown in Fig. 2 shows very small evolution in all distribution projections and moments, whereas the less accurate simulation shows a larger, but still relatively modest degree of evolution due primarily to poor grid resolution and macro-particle statistics (note the large change in scale between the plots). Fluctuations and oscillations associated with the less accurate simulation are still modest considering the coarse numerical parameters employed. This surprisingly benign consequence of errors likely results from both the stability of the underlying steady equilibrium and that the numerical errors seed a broad spectrum of oscillations that remain bounded by initial conditions (system energy is conserved in continuous-focusing) and phase-mix. Differences between the \( x- \) and \( y \)-plane envelope and emittance evolutions as well as nonaxisymmetries in the distribution projections that are clearly evident in the less accurate simulation are related to finite statistics and discretizations breaking ideal symmetries. The initial fluctuations in the density profiles of the accurate simulation are suppressed by both the use of large numbers of macro-particles and by the use of ordered numbers in the load. By the end of the evolution, the statistical noise of the accurate simulation has increased to levels expected if pseudorandom numbers had been employed in the load. It appears that the primary error source in the accurate simulation is the discretization associated with the radial mesh introducing a systematic error in the location of the beam edge which primarily translates into a small amplitude breathing mismatch as evident from the regular, nearly in-phase oscillations of the envelope radii \( r_j \).
FIG. 2: (Color) PIC simulations of an initial waterbag equilibrium distribution in a continuous-focusing channel with \( \sigma_0 = 80^\circ \) and \( \sigma/\sigma_0 = 0.2 \) for a well-converged (two left columns; \( N_c = 100, N_{ppg} = 500 \)) and a less-converged simulation (two right columns: \( N_c = 20, N_{ppg} = 40 \)). In row \( a) \) the evolutions of rms-envelope radii \( [r_j/r_j(s = 0)] \) and rms-edge emittances \( [\varepsilon_j/\varepsilon_j(s = 0)] \) are shown as a function of lattice-periods \( (s/L_p) \). In rows \( b) \) and \( c) \), the principal axis beam density profiles and \( x-x' \) phase-space projections are shown at zero (load) and 20 lattice periods. (WARP simulations with common parameters: \( N_p = 3 \) and \( N_s = 25 \)).

C. Non-equilibrium semi-Gaussian distribution

The semi-Gaussian distribution\[47, 63\] can be defined by

\[
  f_\perp(x_\perp, x_\parallel) = \frac{2\lambda}{q\pi^2\varepsilon_x\varepsilon_y} \Theta \left[ 1 - \left( \frac{x_\parallel^2}{r_x^2} + \frac{y_\parallel^2}{r_y^2} \right) \right] \exp \left[ -2 \left( \frac{r_x x' - r'_x x}{\varepsilon_x} \right)^2 - 2 \left( \frac{r_y y' - r'_y y}{\varepsilon_y} \right)^2 \right].
\]

Here,

\[
  \Theta(x) = \begin{cases} 
    1, & x > 0, \\
    0, & x < 0.
  \end{cases}
\]

is a Heaviside unit-step function, \( r_j \) and \( r'_j \) \( (j = x, y) \) are the initial \( (s = s_i) \) beam envelope radii and angles, and \( \varepsilon_j \) are the initial rms-edge emittances. As for the KV distribution, the density \( n = \int d^2 x' \perp f_\perp \) of the initial distribution is uniform within an ellipse of radii \( r_j \) as given by Eq. (17). Likewise, the coherent flows \( \langle x' \rangle_{x'\perp} \) and \( \langle y' \rangle_{y'\perp} \) are identical to the KV expression in Eq. (19). In contrast to the KV distribution, the incoherent angular spreads in \( x' \) and \( y' \) are spatially uniform and Gaussian-distributed. Direct calculation with Eqs. (14) and (56) shows that the kinetic
temperatures corresponding to the Gaussian-distributed spreads are

\[ T_j = \begin{cases} \frac{x_j^2}{4r_j^2}, & \text{if } (x/r_x)^2 + (y/r_y)^2 < 1, \\ 0, & \text{otherwise.} \end{cases} \] (58)

The semi-Gaussian distribution is not an equilibrium of the Vlasov equation (7) for a linear focusing channel with finite beam space-charge. The distribution will evolve from the initial condition, resulting in a change in form associated with the launching of a transient, nonlinear wave[48, 85]. This wave evolution will result in rms-edge emittance evolutions from the initial conditions \((ε_j \neq \text{const})\) and the subsequent envelope evolution \(r_j(s)\) will only approximately follow that of the KV envelope equation (21).

The strength of the transient evolution of the semi-Gaussian distribution depends primarily on the relative intensity of the applied-focusing and space-charge forces. The initially uniform space-charge within an elliptical beam envelope gives rise to a transient wave that can complicate interpretations of other effects of interest. The initially uniform temperature within the beam results in an unbalanced thermal force inconsistent with the sharp beam edge. The collective wave launched is a manifestation of this inconsistency. Despite this non-equilibrium structure, the semi-Gaussian distribution is commonly employed to model space-charge-dominated beams, with Debye screening expected to lead to a flat density profile for a relaxed distribution. The semi-Gaussian distribution has manifest rms-equivalency with the KV distribution which simplifies interpretation, and the distribution structure corresponds roughly to a beam that would be produced by an ideal injector (uniform current density within the beam emitted from a diode with Child-Langmuir emission[31, 87] and spatially uniform temperature due to a heated source at local thermodynamic equilibrium). It is found that the waves launched by the nonequilibrium form of the semi-Gaussian distribution generally lead to small, space-charge intensity dependent reductions in the rms-edge emittance where the beam is stable[31, 77, 85]. Stability is considered in the sense of having limited wave growth from the initial transient evolution. In the case of stability, transient wave perturbations launched from the initial semi-Gaussian distribution rapidly wash out due to phase-mixing and nonlinear collective effects present for finite space-charge[14, 48, 49, 85]. Semi-Gaussian distributions with \(ε_x \neq ε_y\) (i.e., \(T_x \neq T_y\)) sufficiently anisotropic can lead to evolutions with characteristics of space-charge driven instabilities in situations where the system drives to a more thermally isotropic state[88].

Loading of the initial semi-Gaussian distribution (56) can be carried out using similar steps to those described for the KV distribution in Sec. III A. For direct Vlasov simulations, loading \(f_\perp\) on the phase-space grid is generally less problematic than for a KV distribution because the semi-Gaussian distribution is not singular in 4D phase-space. The most significant issue is the need to adequately represent the sharp elliptical beam edge in \(x_\perp\) on the phase-space grid and to have sufficient resolution in the phase-space mesh to model the nonlinear transient wave launched from the lack of detailed equilibrium force balance[20, 48, 49, 88]. For PIC simulations, particle spatial coordinates \(x_\perp\) can be loaded exactly as discussed for the KV distribution [see Eq. (27)]. Particle angles \(x'_\perp\) can be loaded in terms of coherent and incoherent components terms as \(x'_\perp = x'_\perp|_{\text{ic}} + x'_\perp|_{\text{ic}}\) [see Eq. (28)] with the coherent term \(x'_\perp|_{\text{ic}}\) set exactly as for the KV distribution using Eq. (29), and the incoherent term \(x'_\perp|_{\text{ic}}\) simply set with

\[
x'_\perp|_{\text{ic}} = \frac{ε_x}{2r_x} \hat{g}_x, \quad y'_\perp|_{\text{ic}} = \frac{ε_y}{2r_y} \hat{g}_y, \] (59)

rather than Eq. (31). Here, \(\hat{g}_j\) are independent, Gaussian-distributed random numbers with unit variance. If bounded particle phase-space is necessary, the \(\hat{g}_j\) can be replaced with truncated, Gaussian-distributed values with minimal error if the unit variance Gaussian is truncated for values beyond a few units. Note the similarity of the incoherent load angles specified by Eq. (59) with the formula used to specify the particle angles for the continuous-focusing thermal equilibrium distribution [see Appendix F, Eq. (F22)].

Analogously to the situation discussed for the KV distribution in Sec. III A, the random numbers employed above to load the semi-Gaussian distribution can be replaced by ordered sets of numbers to reduce initial statistical noise. Appropriate sets of ordered Gaussian numbers \(\{\hat{g}_j\}\) can be generated employing the same transforms used to map a uniformly-distributed random number \(\hat{u} \in [0, 1]\) to a Gaussian-distributed random number \(\hat{g}\) with unit variance[89] to ordered sets of \(\{\hat{u}_j\}\).

Examples of Vlasov simulations of initial semi-Gaussian distributions can be found in the literature[20, 48, 49] and will not be repeated here. The ease of loading the semi-Gaussian distribution together with the relative faithfulness of the distribution to the form expected for a cold beam with strong relative space-charge forces has resulted in the semi-Gaussian distribution being the load of choice in many intensive beam simulation studies. The main disadvantage of the semi-Gaussian load is that the lack of approximate force balance near the edge of the beam launches a strong transient wave that can complicate interpretations of other effects of interest.
D. Non-equilibrium distributions of linear-field Courant-Snyder invariants

An alternative non-equilibrium distribution that is a specified function of linear-field single-particle Courant-Snyder invariants of an rms-equivalent beam has been formulated by Batygin[50, 51] building on earlier work[31, 39]. Here we review results under a common notation to aid comparisons to other classes of initial distribution functions. As with the KV (see Sec. III A) and semi-Gaussian (see Sec. III C) distributions, these distributions have elliptical symmetry and consequently can employed in a linear-focusing channel with s-variation in the focusing functions \( \kappa_j \) \((j = x, y)\).

The linear-field Courant-Snyder invariant (LCS) distribution is specified as

\[
f_{\perp}(x_{\perp}, x'_{\perp}, s) = \frac{\lambda}{q} f(A^2),
\]

(60)

where \( f(A^2) \) is any function of the single-particle amplitude

\[
A^2 \equiv \left( \frac{x}{r_{jx}} \right)^2 + \left( \frac{r_{jx} x' - r_{jx} x}{\varepsilon_x} \right)^2 + \left( \frac{y}{r_{jy}} \right)^2 + \left( \frac{r_{jy} y' - r_{jy} y}{\varepsilon_y} \right)^2.
\]

(61)

with \( f \geq 0 \) that satisfies the normalization constraint

\[
\int d^2 x_{\perp} \int d^2 x'_{\perp} f(A^2) = 1,
\]

(62)

and the moment constraint

\[
\int_0^\infty dU \frac{U G(U)}{\int_0^\infty dU G(U)} = \frac{1}{2},
\]

(63)

with

\[
G(U) \equiv \int_U^\infty d\tilde{U} \ f(\tilde{U}).
\]

(64)

The moments \( r_j \) and \( \varepsilon_j \) employed in \( A^2 \) are the statistical envelope radii and emittances of the distribution as defined by Eqs. (23) and (24) in an rms-equivalent beam sense (see Sec. III A). The form of \( A^2 \) and the normalization and moment constraints are sufficient to ensure that the LCS distribution defined by Eqs. (60)–(64) satisfies rms-equivalency for arbitrary (physical) values of \( r_j, r'_j, \) and \( \varepsilon_j \). This rms-equivalency is demonstrated in Appendix C through the use of canonical transformations.

The amplitude \( A^2 \) can be resolved as

\[
A^2 = A^2_x + A^2_y,
\]

(65)

where

\[
A^2_x \equiv \left( \frac{x}{r_{jx}} \right)^2 + \left( \frac{r_{jx} x' - r_{jx} x}{\varepsilon_x} \right)^2,
\]

\[
A^2_y \equiv \left( \frac{y}{r_{jy}} \right)^2 + \left( \frac{r_{jy} y' - r_{jy} y}{\varepsilon_y} \right)^2.
\]

(66)

The amplitudes \( A^2_j \) are single-particle \( j \)-plane Courant-Snyder invariants of a particle evolving within the linear fields (including applied and space-charge) of an rms-equivalent beam (see Appendix B). Consequently, the LCS distribution \( f_{\perp} \propto f(A^2) = f(A^2_x + A^2_y) \) is constant on two-dimensional elliptical surfaces in \( x-x' \) and \( y-y' \) phase-space where \( A^2_j = \) const as well as a four-dimensional ellipsoidal hypersurfaces in \( x_{\perp}-x'_{\perp} \) phase-space where \( A^2 = \) const.

Characteristics of some simple choices of functions \( f(A^2) \) satisfying the normalization constraint (62) and the moment constraint (63) are given in Table II. For the KV case listed, the LCS distribution reduces to the KV equilibrium discussed in Sec. III A and is an exact equilibrium distribution. For any choice of \( f(A^2) \) other than the delta-function KV form, the LCS distribution is not a consistent equilibrium for finite space-charge because the argument \( A^2 \) is a single-particle invariant only for linear space-charge fields within the beam. General choices of \( f(A^2) \) result in density profiles \( n = (\lambda/q) \int d^2 x_{\perp} f \) with nonuniform, elliptic-symmetry density profiles (see Table II). The nonuniform elliptic-symmetry space-charge will generate nonlinear self-field forces within the beam and the \( A^2_j \)
TABLE II: Characteristics of linear-field Courant-Snyder distributions generated for choices of $f(A^2)$. Here, $\xi^2 \equiv (x/r_x)^2 + (y/r_y)^2$.

will evolve, changing the form of the LCS distribution. However, in the limit of vanishing space-charge intensity (i.e., $Q \to 0$), the LCS distributions are exact equilibria for general choices of $f(A^2)$ satisfying Eqs. (62) and (63). In this warm-beam limit the $A^2$ are invariants of a single-particle evolving in linear applied-focusing fields. The warm-beam limit of the LCS distribution with a Gaussian choice of $f$ listed in Table II represents a standard initial particle distribution in accelerator simulations of beams with weak space-charge. Original applications of the LCS distributions appeared to be targeted for use in modeling beams with weak relative space-charge forces by including leading order space-charge corrections by modeling space-charge forces as linear as would arise in a uniform density rms equivalent beam in spite of the actual density distribution of the beam [50, 51]. Discussions and tests presented here cover this original context as well as strong space-charge regimes.

Loading the LCS distribution specified by Eqs. (60)–(64) in a direct Vlasov code is straightforward. The phase-space grid should be chosen to adequately resolve the distribution structure consistent with the choice of $f(A^2)$ made and the ensuing evolution associated with the non-equilibrium form. Distribution projections listed in Table II provide a guide for characteristic resolutions needed for a range of choices in $f(A^2)$.

An elegant procedure to load the LCS distribution using macro-particles in PIC simulations has been formulated by Batygin [50, 51]. This procedure can be summarized as follows. First, canonical transformations analogous to those employed in Appendix C can be applied to calculate the distribution of $A$ in terms of a probability transform. The resulting equation

$$\int_0^{A^2} dU \ U f(U) = \hat{u}_A$$

is solved for the smallest positive real solution $A(\hat{u}_A)$ for a uniformly-distributed random number $\hat{u}_A \in [0, 1]$. The transformation (67) must be solved numerically for general choices of $f$. If a large number of particles are loaded, analogously to the cases discussed in Sec. III B, the transform can be pre-solved on a grid of values for $\hat{u}_A \in [0, 1]$ and interpolation employed for increased numerical efficiency. For the choices of functions $f$ in Table II the transformation (67) can be simplified, and in some cases analytically solved, as indicated. With $A(\hat{u}_A)$ specified, values of $A_x \geq 0$ and $A_y \geq 0$ consistent with $A^2 = A_x^2 + A_y^2$ are set by taking

$$A_x = A \sqrt{\hat{u}_x},$$

$$A_y = A \sqrt{1 - \hat{u}_x},$$

with $\hat{u}_x \in [0, 1]$ an independent, uniformly-distributed random number. This form applies to all choices of $f$ and is taken to statistically represent the total oscillation amplitude $A^2$ equally in the $x$- and $y$-planes [90]. Then, particle phase-space coordinates are set using a phase-amplitude formulation [91] to uniformly populate oscillations in the
elliptical phase-spaces represented by the values of the \( A_j \) by taking

\[
x = A_x r_x \cos \beta_x, \quad x' = A_x \left( r'_x \cos \beta_x - \frac{\varepsilon_x}{r_x} \sin \beta_x \right),
\]
\[
y = A_y r_y \cos \beta_y, \quad y' = A_y \left( r'_y \cos \beta_y - \frac{\varepsilon_y}{r_y} \sin \beta_y \right). \tag{69}
\]

Here, the \( \beta_j \) are betatron phases set as

\[
\beta_j = 2\pi \hat{u}_j, \tag{70}
\]

with independent, uniformly-distributed random numbers \( \hat{u}_j \in [0, 1) \) to uniformly distribute the oscillations in phase about the elliptical symmetry phase-space.

It is worth pointing out that the Gaussian choice of \( f \) indicated in Table II can be loaded using similar methods to those presented in Sec. III C rather than solving the probability transform in Eq. (67) (with the reduced form in Table II). Employing the factorization properties of Gaussian-distributed probability densities, it is straightforward to demonstrate that the Gaussian distribution can be alternatively loaded as

\[
x = \frac{r_x}{2} \hat{g}_x, \quad y = \frac{r_y}{2} \hat{g}_y,
\]
\[
x' = \frac{r'_x}{r_x} x + \frac{\varepsilon_x}{2 r_x} \hat{g}_x', \quad y' = \frac{r'_y}{r_y} y + \frac{\varepsilon_y}{2 r_y} \hat{g}_y'. \tag{71}
\]

Here, \( \hat{g}_j \) and \( \hat{g}_j' \) are Gaussian-distributed (or truncated Gaussian for bounded phase-space as discussed in Sec. III C) random numbers with unit variance.

Analogous to the cases discussed in Secs. III A–III C, the random numbers employed above to load the LCS distributions can be replaced by ordered sets of numbers to reduce initial statistical noise.

Transverse slice PIC simulations illustrating the initial transient (few lattice period) evolution of the LCS distributions in a periodic FODO quadrupole transport channel are shown in Figs. 3–5. Evolutions associated with both waterbag and Gaussian choices of the function \( f \) listed in Table II are shown. The simulations and parameter choices are described in Sec. II and the beam envelope is initially rms-envelope matched to the FODO lattice\(^{[75]} \). Simulations are shown for weaker (\( \sigma_0 = 45^\circ \)) and stronger (\( \sigma_0 = 70^\circ \)) applied-focusing strengths, each case for weak (\( \sigma/\sigma_0 = 0.9 \)) and strong (\( \sigma/\sigma_0 = 0.2 \)) relative space-charge strength. These values are selected to be parametrically removed from regions where beam transport in periodic alternating-gradient focusing channels is expected to become unstable due to the intrinsic structure of orbits near the beam edge\(^{[15, 33]} \). Loads are generated for the waterbag \( f \) case using uniformly-distributed pseudo-random numbers \( \text{[employing the analytic probability transform in Table II and Eqs. (68)–(70)]} \) and Gaussian-distributed pseudo-random numbers in the Gaussian \( f \) case \( \text{[using Eq. (71)]} \). Initial distribution projections numerically calculated by binning particles loaded were checked against analytically calculated projections \( \text{[see Table II]} \) to verify the validity of numerical procedures employed. Also the Gaussian distribution loading method based on Eq. (71) was carefully cross-checked against the transform method using results in Table II and Eqs. (68)–(70)]. High particle statistics are employed so the evolution of the beam density \( \text{(shown every lattice period)} \) can be observed with minimal noise. Only modest statistics are necessary for converged emittance evolutions.

The simulations clearly illustrate the expected result: that for weak relative space-charge forces \( (\sigma/\sigma_0 \sim 1) \) the LCS distributions are fairly well adapted to the transport channel and the subsequent evolutions of the distributions from the initial state are relatively small, whereas for large relative space-charge forces \( (\sigma/\sigma_0 \text{ small}) \) the lack of local force balance associated with the inconsistent use of linear-field Courant-Snyder invariants to define the distributions sets up strong, transient-wave perturbations. This effect is clearly seen in the density profile evolutions in Fig. 3. In these plots, profiles of the beam density \( n \) along the principal \( x \)- and \( y \)-axes are calculated from the gridded charge density in the simulation with no additional smoothing. The beam density is normalized by an rms average measure, \( \lambda/(q\pi r_x r_y) \), so values not equal to unity indicate deviations from an rms equivalent KV beam. Density profiles are shown at each lattice period of the evolution (in separate colors) with variations indicating deviations from periodic equilibrium conditions rather than numerical errors. Profiles along the \( x \)- and \( y \)-axes are shown in separately, because the evolution introduces asymmetries between the planes. Evolutions in the rms edge emittances \( \varepsilon_j \) corresponding to the density evolutions in Fig. 3 are shown in Fig. 4. The emittances are calculated from Eq. (24) with the \( x \)- and \( y \)-emittances shown in black and red. Note that the \( x \)- and \( y \)-plane evolutions in both the density profiles and emittances vary between the planes due to both the phase of the launching condition of the load within the lattice.
period (taken between quadrupoles) and the lack of system axisymmetry (i.e., $\partial/\partial \theta \neq 0$). The $x$- and $y$-emittances tend to evolve out of phase and plane average emittances [i.e., $(\varepsilon_x + \varepsilon_y)/2$ or $\sqrt{\varepsilon_x \varepsilon_y}$] evolve less but are not conserved. System (beam kinetic plus total field) energy need not be conserved because the applied-focusing lattice can pump energy into the system. However, if rms-matching is maintained, system energy is approximately conserved in an average sense over multiple lattice periods. Phase-space projections at lattice period intervals for one evolution are shown in Fig. 5. The $x-y$, $x-x'$, and $y-y'$ projections illustrate further characteristics of the large waves launched due to the lack of force balance in the beam distribution when space-charge is strong. In the $x-x'$ projections, $x'$ represents $x' = r'_x(x/r_x)$ with $r_x$ and $r'_x$ calculated from Eq. (23) (i.e., in an rms equivalent beam sense). This transformation removes the tilt angle of the ellipse associated with the coherent flow while conserving local $x-x'$ phase-space area and thereby better illustrate distribution distortions. An analogous transformation is made in the $y-y'$ projections. A random sampling of particles are plotted to represent the distribution. Colors of the plotted particles represent relative densities of the projections as indicated (in arb. units).

Despite the strength of the transient evolution for strong space-charge, the rms-envelope radii $r_j$ of the distributions remain well matched to the focusing lattice and the emittance evolutions are relatively modest. This is not surprising given that choices of initial distributions even further out of local force balance are also observed to remain relatively well matched with modest emittance growth[14]. Waves launched by the lack of local consistency in the initial distribution tend to drive the profile to a more uniform density beam through phase-mixing, Landau-damping, and nonlinear interactions. Such relaxations tend to result in increased beam emittance because the more uniform profiles have lower field energy and the energy difference between the initial and relaxed state (in an approximate sense: $x$-varying focusing forces can also pump energy into and out of the beam during the period and details of such processes can vary especially in the initial transient evolution) is available to drive increases in incoherent spreads[14, 31, 63]. Longer simulations suggest that the distribution can relax to a state better adapted to the transport channel with significant, but reduced spectrum of residual oscillations persisting. The relaxed state tends to be more nearly plane equilibrated with $\varepsilon_x \sim \varepsilon_y$. Propagation distances necessary for relaxation can be significant and are difficult to determine because the relaxation distance varies with the strength of the applied-focusing ($\sigma_0$) and the relative space-charge strength ($\sigma/\sigma_0$). Numerical approximations can also induce effective, nonphysical relaxations that are difficult to separate from other processes. This can further complicate the relaxation issue: very large simulations can be necessary for proper, physical convergence. Batygin has explored alternative techniques where nonlinear terms can be added to the applied focusing forces so that the total applied plus space-charge force acting on the particles is linear, and then adiabatically decreasing the applied nonlinear force[54]. In any event, for strong relative space-charge forces it is desirable to generate improved, but still relatively simple loads with smooth distributions that are more equilibrium-like with lesser transient wave evolution to simplify applications and interpretation of results. This issue is addressed in Sec. IV.
FIG. 3: (Color) Transient evolution of the beam density $n$ of initial LCS distribution loads for: a) waterbag $f$, $\sigma_0 = 45^\circ$, $\alpha/\sigma_0 = 0.9$; b) waterbag $f$, $\sigma_0 = 45^\circ$, $\alpha/\sigma_0 = 0.2$; c) waterbag $f$, $\sigma_0 = 70^\circ$, $\alpha/\sigma_0 = 0.9$; d) waterbag $f$, $\sigma_0 = 70^\circ$, $\alpha/\sigma_0 = 0.2$; e) Gaussian $f$, $\sigma_0 = 45^\circ$, $\alpha/\sigma_0 = 0.9$; f) Gaussian $f$, $\sigma_0 = 45^\circ$, $\alpha/\sigma_0 = 0.2$; g) Gaussian $f$, $\sigma_0 = 70^\circ$, $\alpha/\sigma_0 = 0.9$; and h) Gaussian $f$, $\sigma_0 = 70^\circ$, $\alpha/\sigma_0 = 0.2$. Density profiles are shown along the principal $x$- and $y$-axes at lattice period intervals. (B-DYN: $N_r = 50$, $N_{ppg} = 4k$, $N_s = 100$, $N_p \simeq 3$)
FIG. 4: (Color) Evolution of the beam rms edge emittances $\varepsilon_x$ and $\varepsilon_y$ as a function of lattice periods ($s/L_p$) for the simulations shown in Fig. 3.
FIG. 5: (Color) Evolution of phase-space projections in $x-y$, $x-x'$, and $y-y'$ for the initial LCS waterbag distribution shown in Figs. 3 and 4 with $\sigma_0 = 70^\circ$ and $\sigma/\sigma_0 = 0.2$. Projections (columns) are shown at lattice period intervals (rows).
IV. PSEUDO-EQUILIBRIUM DISTRIBUTIONS

It is desirable to improve on the classes of specified kinetic distributions reviewed in Sec. III for Vlasov simulations of unbunched or weakly bunched beams with high space-charge intensity in non-constant linear focusing lattices. Here, we present a class of “pseudo-equilibrium” distributions\[64\] that are simple to specify, and can have both smooth core structure and more nearly equilibrium-like properties that would be expected for an initial beam better adapted to a linear transport channel. The procedure (Sec. IV A) is conceptually simple to formulate and builds on the results in Sec. III. Beam slices are specified by rms equivalent parameters, which are then mapped to a local rms matched continuous focusing equilibrium distribution with self-consistent Debye screening. The distribution is then transformed back to a form more appropriate for non-constant linear focusing forces. Following the description of the method, example pseudo-equilibrium loads are self-consistently simulated (Sec. IV B) in a periodic FODO quadrupole transport channel to illustrate results. The simulations verify improved, closer to equilibrium-like properties of the pseudo-equilibrium distributions relative to the standard distributions reviewed in Sec. III.

The pseudo-equilibrium procedure is formulated for a beam in an applied-focusing lattice with linear-focusing functions \(\kappa_j(s)\) that can vary arbitrarily in \(s\) \((\kappa_j \neq \text{const}; \ j = x, y)\). Nonlinear (or skew coupled) applied-field components can exist but are ignored in the specification of the \(\kappa_j\) (a proper inclusion would greatly complicate the formulation since it would require the application of more complicated Courant-Snyder forms; see Ref. [92]). The beam need not be rms “matched” to the linear-focusing lattice and the procedure can be applied to generate transverse or full 3D beam distributions when axial variations are sufficiently slow where self-fields can be approximated as 2D transverse fields. For either the 2D or 3D case, axial phase-space coordinates of the particles are regarded as specified (in the \(s\)-slice for transverse loads). The pseudo-equilibrium distribution is assumed to have the form

\[
f = f_\perp(x, x'; s) f_z(z, p_z),
\]

where \(z\) and \(p_z\) are the longitudinal particle coordinate and momentum and \(f_z \geq 0\) is the longitudinal distribution. The connection between \(s\) and \(z\) must be specified and the total number of particles within the beam \(N = \int dz dp_z \int d^2x_\perp \int d^2x'_\perp f\) sets the normalization of \(f_z\). A variety of longitudinal distributions \(f_z\), such as the Neuffer distribution\[93\], can be applied to model the beam ends.

A. Pseudo-Equilibrium Procedure

In the pseudo-equilibrium procedure, initial transverse particle phase-space coordinates \((x, y, x', y')\) are loaded as follows.

**Step 1:** For each particle at axial coordinate \(s\), specify the beam perveance

\[
Q(s) = \frac{g\lambda(s)}{2\pi\epsilon_0 mc^2\gamma_0^2\beta_0^2},
\]

statistical beam edge radii

\[
r_x(s) = 2\langle x^2 \rangle_\perp^{1/2}, \quad r_y(s) = 2\langle y^2 \rangle_\perp^{1/2},
\]

equation angles

\[
r_x'(s) = \frac{2\langle xx' \rangle_\perp}{\langle x^2 \rangle_\perp^{1/2}}, \quad r_y'(s) = \frac{2\langle yy' \rangle_\perp}{\langle y^2 \rangle_\perp^{1/2}},
\]

and rms-edge emittances

\[
\varepsilon_x(s) = 4 \left[ \langle x^2 \rangle_\perp \langle x^2 \rangle_\perp - \langle xx' \rangle_\perp^2 \right]^{1/2},
\]
\[
\varepsilon_y(s) = 4 \left[ \langle y^2 \rangle_\perp \langle y^2 \rangle_\perp - \langle yy' \rangle_\perp^2 \right]^{1/2}.
\]

For a given beam ion and slice energy, Eqs. (74)–(73) fix the beam line-charge \(\lambda\) and the 2nd-order moments \(\langle x^2 \rangle_\perp, \langle x^2 \rangle_\perp, \langle xx' \rangle_\perp\) (and corresponding \(y\)-plane moments) in terms of \(Q, r_j, r'_j, \) and \(\varepsilon_j\). In this specification, we have not assumed that the linear focusing functions \(\kappa_j(s)\) are periodic. If the \(\kappa_j\) are periodic, the envelope
radii $r_j$ need not be matched to the focusing lattice. The mean axial factors $\beta_b$ and $\gamma_b = 1/\sqrt{1 - \beta^2_b}$ are set consistently with the longitudinal distribution of particles being loaded with

$$\beta_b = \langle \frac{v_s}{c} \rangle_{v_z}. \quad (77)$$

Here, $\langle \cdots \rangle_{v_z}$ denotes an average over the axial beam velocity $v_z$ calculated at axial slice location $s$. The paraxial approximation of small longitudinal velocity spread is assumed to apply. In cases where a long beam is accelerating and/or longitudinally compressing/expanding, a prescribed head-to-tail $s$-variations in $\beta_b$ is permitted over the axial length of the beam insofar as the fractional change is small.

Step 2: Define an rms-matched, continuously-focused beam for each particle with permeance $Q(s)$, statistical edge envelope radius

$$r_b(s) = \sqrt{r_x(s)r_y(s)}, \quad (78)$$

rms-edge emittance

$$\varepsilon_b(s) = \sqrt{\varepsilon_x(s)\varepsilon_y(s)}, \quad (79)$$

and focusing-field strength

$$k^2_{30}(s) = \frac{Q(s)}{r^2_b(s)} + \frac{\varepsilon^2_b(s)}{r^2_b(s)}. \quad (80)$$

The choices in Eqs. (78)–(80) are consistent with approximating the KV envelope equations (21) as an average force-balance equation with: $r_j = r_b$, $\kappa_j = k^2_{30}$, and $\varepsilon_j = \varepsilon_b$ where we treat $r_b$ as slowly varying (i.e., $r''_b$ negligible in the envelope equation). Alternatively, the geometric-mean definitions made in Eq. (78) and Eq. (79) can be replaced with arithmetic-mean measures [e.g., $r_b = (r_x + r_y)/2$ rather than $r_b = \sqrt{r_x r_y}$] resulting in only small differences in typical applications where beams are not highly elliptical (i.e., $r_x \sim r_y$) and are nearly plane equilibrated (i.e., $\varepsilon_x \approx \varepsilon_y$). However, the geometric-mean definitions apply more logically in the general cases since they reflect an equivalence of beam cross-sectional area and four-dimensional phase-space volume.

Step 3: For the rms-matched, continuously-focused transverse distribution defined in Step 2, specify an axisymmetric (i.e., $\partial/\partial \theta \neq 0$) Vlasov equilibrium distribution

$$f_\perp(x, y, x', y'; s) = f_\perp[H_\perp(s)] \quad (81)$$

with a particular functional form $f_\perp(H_\perp)$ (e.g., waterbag, parabolic, thermal, ...). Here,

$$H_\perp(s) = \frac{1}{2} x^2_\perp + \frac{1}{2} k^2_{30} x^2_\perp + \frac{q}{m\gamma^2_b \beta^2_b c^2} \phi \quad (82)$$

is the transverse Hamiltonian of a beam particle and parameters employed in the definition of $f_\perp(H_\perp)$ are constrained by

$$\lambda(s) = q \int d^2x_\perp \int d^2x'_\perp f_\perp(H_\perp),$$

$$r^2_b(s) = \frac{4 \int d^2x_\perp \int d^2x'_\perp x^2 f_\perp(H_\perp)}{\int d^2x_\perp \int d^2x'_\perp f_\perp(H_\perp)}, \quad (83)$$

$$\frac{\varepsilon^2_b(s)}{r^2_b(s)} = \frac{4 \int d^2x_\perp \int d^2x'_\perp x^2 f_\perp(H_\perp)}{\int d^2x_\perp \int d^2x'_\perp f_\perp(H_\perp)}. \quad (84)$$

Generally, a function $f_\perp(H_\perp)$ satisfying the monotonicity condition $\partial f_\perp(H_\perp)/\partial H_\perp \leq 0$ is preferable to correspond to a stable core distribution in the continuous limit\cite{30, 32}. The procedure for implementing the constraints in Eq. (83) will generally be complex because $\phi$ occurring in $H_\perp$ must be calculated self-consistently with the transverse Poisson equation [see Eq. (33)]

$$\frac{1}{r} \frac{\partial}{\partial r} r \frac{\partial}{\partial r} \phi = - \frac{q}{\varepsilon_0} \int d^2 x'_\perp f_\perp(H_\perp). \quad (84)$$
for each beam slice for 3D beams. Careful analysis and scaling can reduce the number of free parameters and numerical work necessary to calculate $\phi$ and implement the constraints associated with particular choices of equilibrium functions $f_\perp(H_\perp)$. Formulating efficient procedures is especially important in 3D applications because constraints may need to be applied to each particle independently (each particle can be in a different transverse slice of the beam). Gridded transforms can be generated (see Sec. III B) for the needed range of equilibrium parameters to reduce numerical work. For the case of transverse applications, the constraints need only be solved once rendering efficiency issues much less important. Special numerical methods can prove necessary in analyzing the constraints for strong space-charge. When space-charge becomes sufficiently strong, Debye screening results in the radial density profile interior to the beam becoming very flat and the beam edge sharp (see Appendices D–F).

**Step 4**: Load the transverse particle phase-space coordinates $x$, $y$, $x'$, $y'$ consistent with the continuous distribution calculated in step 3 (see discussions in Sec. III B).

**Step 5**: Transform the axisymmetric distribution particle coordinates loaded in step 4 to local rms-equivalency in the slice of the beam. This can be accomplished with a two-step procedure by first transforming the particle coordinates as

$$
x \rightarrow x = \frac{r_x}{r_b} x,
\frac{y}{y} \rightarrow y = \frac{r_y}{r_b} y,
$$

and then (with the first step carried out) transforming the particle angles as

$$
x' \rightarrow x' = \frac{\varepsilon_x}{r_x} \frac{r_b^2}{r_b^2} x' + \frac{r'_{x}}{r_x},
y' \rightarrow y' = \frac{\varepsilon_y}{r_y} \frac{r_b^2}{r_b^2} y' + \frac{r'_{y}}{r_y}.
$$

Denoting initial/final particle coordinates with a subscript/superscript $i/f$, this transform can be carried out in a single step as ($y$-plane expressions analogous):

$$
x_i = \frac{r_x}{r_b} x_i,
y_i = \frac{\varepsilon_x}{r_x} \frac{r_b^2}{r_b^2} x_i + \frac{r'_{x}}{r_x},
y_i = \frac{\varepsilon_y}{r_y} \frac{r_b^2}{r_b^2} y_i + \frac{r'_{y}}{r_y}.
$$

These transforms preserve linear-force Courant-Snyder invariants of the particle distribution (see Appendix B).

The transverse beam density $n = \int d^2 x_\perp f_\perp$ of the initial pseudo-equilibrium distribution generated by this procedure will have $n = \text{const}$ on elliptical surfaces with $(x/r_x)^2 + (y/r_y)^2 = \text{const}$ within the beam. However, in contrast to the KV distribution, the density profile of the pseudo-equilibrium distribution will have radial structure in $(x/r_x)^2 + (y/r_y)^2$ with an edge profile that reflects the choice of $f_\perp(H_\perp)$ made. For monotonic $f_\perp(H_\perp)$ and strong space-charge, Debye screening will lead to a flat charge profile within the core of the beam that falls off in a few characteristic Debye lengths near the edge where $(x/r_x)^2 + (y/r_y)^2 \sim 1$. The specific structure of the edge (the rapidity of the fall-off, whether it reduces to zero or exponentially small values, etc.), will depend on the functional form of $f_\perp(H_\perp)$ chosen. The pseudo-equilibrium distribution is exact for the case of an ideal, continuous-focusing system (see Sec. III B). For $s$-varying focusing lattices the initial pseudo-equilibrium distribution will not be an exact equilibrium (except when $f_\perp(H_\perp)$ is chosen to correspond to a continuous-focusing KV distribution) and some initial transient evolution is expected. For stronger focusing (larger $\sigma_0$), this transient is expected to become more pronounced because stronger focusing will generally be more poorly approximated by the continuous limit. For sufficiently large $\sigma_0$, the beam is expected to become destabilized for any choice of $f_\perp(H_\perp)$[15]. It should again be stressed that although the underlying continuous distribution $f_\perp(H_\perp)$ used in the construction of the pseudo-equilibrium distribution are rms-matched, the resulting pseudo-equilibrium distribution applies to arbitrary $s$-varying focusing lattices. If the lattice focusing functions are periodic, the initial pseudo-equilibrium distribution can be envelope-matched or envelope-mismatched, depending on the choice of $r_j$ made.
The pseudo-equilibrium loading procedure outlined in Sec. IV A is implemented in the WARP and B-DYN PIC codes for underlying continuous waterbag, and thermal equilibrium distributions. Example transverse slice PIC simulations illustrating the initial transient evolution of the pseudo-equilibrium distributions in a periodic FODO quadrupole transport channel are presented in Figs. 6–9 for distributions with underlying waterbag and thermal equilibrium form. Codes and parameter choices are described in Sec. II, and data is presented using analogous procedures and formats as presented in Secs. III B and III D. Exceptions to this correspondence are explicitly noted. Simulations are shown for weaker ($\sigma_0 = 45^\circ$) and stronger ($\sigma_0 = 70^\circ$) applied-focusing strengths, each for weak ($\sigma/\sigma_0 = 0.9$) and strong ($\sigma/\sigma_0 = 0.2$) relative space-charge strength. These values are selected to be parametrically removed from regions where alternating-gradient transport is expected to become unstable resulting from the intrinsic structure of orbits near the beam edge in periodic systems with strong space-charge[15, 33]. Beams are initially rms-envelope-matched to the transport channel[75]. In all simulations digit-reversed numbers are used to generate macro-particle loads with lower statistical noise to allow better visualization of collective wave evolution. Also, large numbers of macro-particles are simulated to allow clear visualization of density profile evolutions with limited noise – only relatively modest numbers of macro-particles are necessary for converged emittance evolutions. The radial probability transform (see discussion in Sec. III B) needed to load the particle coordinates are solved on a uniform mesh of 500 points with a cutoff set at the beam edge in the waterbag case and where the density become exponentially small in the thermal case. Short (few-lattice-period) evolutions are simulated to display initial transient evolutions characteristic of non-equilibrium behavior. We generally find that long evolutions are not problematic (negligible emittance growth with particles remaining well confined in the beam core without large changes in distribution structure) if parameters are chosen sufficiently far from regions where the system is expected to be unstable[15, 33].

Comparing the results in Figs. 6–9 for the pseudo-equilibrium distributions to the results presented in Sec. III D for analogous linear-field Courant-Snyder invariant distributions, it is clear that the pseudo-equilibrium distributions are much better adapted to the applied-focusing channel – particularly for stronger relative space-charge strength. Although collective wave perturbations are still launched from the initial pseudo-equilibrium distributions, the strength of residual waves launched from the lack of detailed equilibrium form are significantly reduced indicating an initial beam that is better adapted to the transport channel. This improved adaptation is particularly apparent for cases of high space-charge intensity when contrasting the density profile evolutions in Figs. 3 and 6. Simulations of initial pseudo-equilibrium distributions with weaker applied focusing (i.e., smaller $\sigma_0$) and weaker relative space-charge strength (i.e., higher $\sigma/\sigma_0$) have evolutions closer to equilibrium form with the distribution projections nearly periodically repeating with each lattice period. Evolutions in the rms edge emittances $\varepsilon_j$ are relatively small in all cases of the pseudo-equilibrium distributions because the evolutions in the charge density profile are modest. Simulation cases in Figs. 6 and 7 that are not shown in the phase-space projections in Figs. 8 and 9 have smaller deviations. In these projections plots a numerical method is employed that shows almost all particles in the low-density regions and a sampling of particles in the high-density regions. This enhances visualization of perturbations near the edge of the beam relative to the sampling method employed in the corresponding phase-space projection plots in Sec. III D. Phase-space projections of the waterbag form pseudo-equilibrium distribution are shown rather than projections of the thermal form pseudo-equilibrium distribution because the sharp phase-space boundary of the waterbag distribution (along with plotting essentially all particles near the edge) makes it easier to visualize waves associated with the lack of equilibrium form which manifest most strongly near the beam edge. In all cases, waves are launched due to lack of exact force balance in near the radial edge of the beam distribution as the beam evolves in the alternating gradient focusing structure. Note in Figs. 8–9 that wave perturbations are primarily launched near the edge of the distribution and only weakly perturb the core while distorting the low-density region near the beam edge most. Emission evolutions shown in Fig. 7 are small in all cases examined – as should be expected because charge redistributions are modest and the beam envelope remains rms-envelope matched to high accuracy[14, 31].

Although the pseudo-equilibrium distributions are not exact equilibria, the underlying smooth continuous-focusing distributions reflect self-consistent space-charge screening and stable functional forms in the continuous limit that are expected to have less free energy relative to the KV distribution to drive wave-like instabilities. In terms of waves launched from the lack of detailed equilibrium form, the pseudo-equilibrium distributions also exhibit improved performance relative to other non-equilibrium ansatz type initial distributions such as the semi-Gaussian (see Sec. III C) and linear-field Courant-Snyder invariant (see Sec. III D) distributions that are commonly in use. These properties render the pseudo-equilibrium distributions useful in probing intrinsic space-charge-related transport limits of periodic focusing channels. Parametric simulation studies carried out with the pseudo-equilibrium loads have already been applied as part of a study to better understand space-charge related transport limits in quadrupole focusing channels[15]. Finally, it should be stressed that the pseudo-equilibrium distribution loads are not only applicable to periodic alternating-gradient focusing channels. The procedure applies to any lattice with $s$-varying or constant applied-focusing forces described by the focusing functions $\kappa_j(s)$. A simple periodic FODO lattice is employed here
only for simplicity of illustration and for demanding test cases. One might expect the procedure for constructing the pseudo-equilibrium distributions to work even better in the sense of approximating equilibrium properties because particle orbits in high-occupancy solenoidal transport systems are generally better approximated by particle orbits in the continuous-focusing model relative to orbits in strong (quadrupole) focusing systems. The pseudo-equilibrium distributions can also be applied to simulate beam transition and matching sections, or other aperiodic transport lattices. As with the case of periodic systems, significantly better performance can be expected for aperiodic lattices with the pseudo-equilibrium distributions when space-charge intensity is high.
FIG. 6: (Color) Transient evolution of the beam density $n$ of initial pseudo-equilibrium distribution loads for: a) waterbag form: $\sigma_0 = 45^\circ$, $\sigma/\sigma_0 = 0.9$, b) waterbag form: $\sigma_0 = 45^\circ$, $\sigma/\sigma_0 = 0.2$, c) waterbag form: $\sigma_0 = 70^\circ$, $\sigma/\sigma_0 = 0.9$, d) waterbag form: $\sigma_0 = 70^\circ$, $\sigma/\sigma_0 = 0.2$, e) thermal form: $\sigma_0 = 45^\circ$, $\sigma/\sigma_0 = 0.9$, f) thermal form: $\sigma_0 = 45^\circ$, $\sigma/\sigma_0 = 0.2$, g) thermal form: $\sigma_0 = 70^\circ$, $\sigma/\sigma_0 = 0.9$, h) thermal form: $\sigma_0 = 70^\circ$, $\sigma/\sigma_0 = 0.2$. Density profiles are shown along the principal $x$- and $y$-axes at lattice period intervals. (WARP: $N_t = 50$, $N_{ppg} = 40k$, $N_s = 100$, $N_p \approx 3$)
FIG. 7: Evolution of the beam rms edge emittances $\varepsilon_x$ and $\varepsilon_y$ as a function of lattice periods ($s/L_p$) for the simulations shown in Fig. 6.
FIG. 8: (Color) Evolution of phase-space projections in $x$–$y$, $x$–$x'$, and $y$–$y'$ for the initial pseudo-equilibrium waterbag distribution simulation shown in Figs. 6 and 7 with $\sigma_0 = 45^\circ$ and $\sigma/\sigma_0 = 0.2$. Projections (columns) are shown at lattice period intervals (rows).
FIG. 9: (Color) Evolution in phase-space projections in $x-y$, $x-x'$, and $y-y'$ for the initial pseudo-equilibrium waterbag distribution simulation shown in Figs. 6 and 7 with $\sigma_0 = 70^\circ$ and $\sigma/\sigma_0 = 0.2$. Projections (columns) are shown at lattice period intervals (rows).
V. CONCLUSIONS

Standard classes of distributions commonly in use for initializing transverse Vlasov simulations of charged particle beams with intense space-charge were reviewed in this paper, including: the KV equilibrium distribution; continuous-focusing equilibria, with detailed examples for “waterbag,” “parabolic,” and “thermal” forms; the non-equilibrium semi-Gaussian distribution; and non-equilibrium distributions of linear-field Courant-Snyder invariants. All distributions were presented within a common notation and prescriptions were given to generate macro-particle distributions for loading PIC simulations. Care was taken to formulate the presentation in terms of usual accelerator variables (perveances, rms-emittances, etc.) rather than special theoretical parameters not in common use, to render methods directly applicable to standard accelerator problems. Procedures were developed to specify loads over the full range of space-charge strength – even for continuous-focusing equilibria where strong relative space-charge strength can present practical difficulties. Deficiencies of the various distributions for use in modeling linear-focusing channels with non-continuous focusing forces were discussed and illustrative Vlasov PIC simulations were presented for initial distributions not already detailed in the literature.

Following this review, a new class of pseudo-equilibrium distribution functions were derived, building on the standard classes of distributions reviewed. The pseudo-equilibrium distributions were formulated to satisfy the need of a more equilibrium-like, yet simple, smooth distribution to apply in simulations of intense beams in focusing channels with linear applied-forces that vary arbitrarily (other than excluding skew couplings) in the axial coordinate $s$. The pseudo-equilibrium distributions are not exact equilibria of a linear-focusing channel with non-constant applied-focusing forces, but they are relatively simple to formulate and have appealing physical properties expected for a relaxed beam evolving in a linear-focusing channel with space-charge driven Debye screening. The cores of the pseudo-equilibrium distributions are specified by any, stable continuous-focusing equilibrium beam. Transformations that preserve linear-field Courant-Snyder invariants are then applied to map these continuous distributions to a form more appropriate for focusing channels with $s$-varying applied-focusing forces. Details are presented to generate pseudo-equilibrium distributions with underlying waterbag, parabolic, and thermal equilibrium continuous-focusing forms – which cover a wide range of phase-space structure. Illustrative Vlasov PIC simulations were carried out to evolve transverse pseudo-equilibrium loads in a periodic FODO quadrupole focusing channel to explicitly demonstrate the advantages of the smooth core structure in terms of diminished transient waves relative to more standard initial distributions. This more quiescent behavior can aid understanding of detailed transport physics. The pseudo-equilibrium procedure can be applied to load both 2D transverse slice as well as full 3D (with specified longitudinal structure) distributions. Also, relaxation methods can be applied to initial pseudo-equilibrium loads to further improve the adaptation of the beam in the sense of being more equilibrium like. Considerable opportunities still exist for future research in equilibrium-like loads in linear focusing channels with non-constant focusing forces — both in terms of the intrinsic existence or non-existence of smooth Vlasov equilibrium distribution functions and in construction of better approximate loads through improved physical insight or systematic perturbation theory.

ACKNOWLEDGMENTS

The authors wish to thank: D.P. Grote and J.-L. Vay for assistance with the WARP simulations and helpful discussions; J.J. Barnard, Y.K. Batygin, A. Friedman, and S. Kawata for guidance and helpful discussions. This research was performed under the auspices of the U.S. Department of Energy at the Lawrence Livermore National Laboratory under contract No. W-7405-Eng-48, at Princeton Plasma Physics Laboratory under contract No. DE-ACO2-76-CHO-3073, and by JSPS (Japan Society for the Promotion of Science) and MEXT (Ministry of Education, Culture, Sports, Science, and Technology). Part of the research was carried out during visits by S.M. Lund to Utsunomiya University and reciprocal visits by T. Kikuchi to Lawrence Berkeley National Laboratory.* These visits were part of an ongoing series of Japan-U.S exchanges on heavy ion fusion and high energy density physics.

APPENDIX A: ACCELERATION EFFECTS

In the absence of axial beam acceleration, $\gamma_b \beta_b = \text{const}$ and the particle equation of motion in the $x$-direction that is produced by the Hamiltonian (8) is

$$x'' + \kappa_x x = -\frac{q}{m \gamma_b \beta_b c^2} \frac{\partial \phi}{\partial x}.$$  (A1)
If $\gamma_0/b_0$ is allowed to vary slowly in $s$ consistent with axial acceleration forces acting on the beam, then the equation of motion (A1) is modified as

$$x'' + \frac{(\gamma_0/b_0)'}{(\gamma_0/b_0)} x' + \kappa_x x = -\frac{q}{m\gamma_0^2b_0^2c^2} \frac{\partial \phi}{\partial x}. \quad (A2)$$

For $(\gamma_0/b_0)' > 0$, one may deduce from Eq. (A2) and analysis of damped harmonic oscillators[94] that the acceleration will tend to damp particle oscillations. Analogous equations hold in the $y$-plane both here and in subsequent equations.

A transformation to tilde variables is defined by taking[63, 95]

$$\tilde{x} = \sqrt{\gamma_0b_0}x. \quad (A3)$$

Then

$$\tilde{x}' = \sqrt{\gamma_0b_0} x' + \frac{1}{2} \frac{(\gamma_0/b_0)'}{(\gamma_0/b_0)} x, \quad (A4)$$

and the particle $x-x'$ phase-space coordinates are related to the $\tilde{x}-\tilde{x}'$ coordinates by

$$x = \frac{1}{\sqrt{\gamma_0b_0}} \tilde{x},$$

$$x' = \frac{1}{\sqrt{\gamma_0b_0}} \tilde{x}' - \frac{1}{2} \frac{(\gamma_0/b_0)'}{(\gamma_0/b_0)^{3/2}} \tilde{x}. \quad (A5)$$

Some straightforward manipulation then shows that the equation of motion (A2) can be expressed as

$$\tilde{x}'' + \left[\kappa_x + \frac{1}{4} \frac{(\gamma_0/b_0)'^2}{(\gamma_0/b_0)^2} - \frac{1}{2} \frac{(\gamma_0/b_0)''}{(\gamma_0/b_0)^2} \right] \tilde{x} = -\frac{q}{m\gamma_0^2b_0^2c^2} \frac{\partial \tilde{\phi}}{\partial \tilde{x}}. \quad (A6)$$

A transformed potential $\tilde{\phi}$ is defined as

$$\tilde{\phi} = \gamma_0b_0\phi. \quad (A7)$$

Then the equation of motion (A6) becomes

$$\tilde{x}'' + \tilde{\kappa}_x \tilde{x} = -\frac{q}{m\gamma_0^2b_0^2c^2} \frac{\partial \tilde{\phi}}{\partial \tilde{x}}, \quad (A8)$$

where

$$\tilde{\kappa}_x \equiv \kappa_x + \frac{1}{4} \frac{(\gamma_0/b_0)'^2}{(\gamma_0/b_0)^2} - \frac{1}{2} \frac{(\gamma_0/b_0)''}{(\gamma_0/b_0)^2}. \quad (A9)$$

is a linear-focusing function that incorporates acceleration effects.

The equivalence of form of between the equations of motion (A2) and (A8) show that the formulation with $\gamma_0b_0 = $ const can be applied to accelerating beams if the particle phase-space coordinates are interpreted consistently with the transformations in Eqs. (A3)–(A4). Note that in a periodic applied-focusing lattice, if the beam is to remain envelope matched in the usual sense, Eq. (A9) shows that the focusing functions $\kappa_j$ ($j = x, y$) must, in general, be adjusted such that the $\tilde{\kappa}_j$ maintain proper periodicity with $\tilde{\kappa}_j(s + L_p) = \tilde{\kappa}_j(s)$. For a lattice with discrete acceleration gaps and separated function magnets for beam focusing, this can be done approximately when the fractional gain in particle energy through each acceleration gap is small.

The transformation defined by Eqs. (A3)–(A4) is straightforward to interpret. The Jacobian of the transformation shows that phase-space area elements are related as

$$d\tilde{x} \otimes d\tilde{x}' = \gamma_0b_0 dx \otimes dx'. \quad (A10)$$

The $\gamma_0b_0$ factor compensates for acceleration induced damping in $x-x'$ phase-space. If the transformed equations of motion are linear, then single-particle Courant-Snyder invariants exist in $\tilde{x}-\tilde{x}'$ phase-space (see Appendix B), but the phase-space area associated with the Courant-Snyder invariant will be damped by the factor $1/(\gamma_0b_0)$ in $x-x'$ phase-space. This is the reason for the conventional application of normalized emittances that incorporate the $\gamma_0b_0$ factor when measuring the phase-space area in accelerating beams[31, 63, 96].
Finally, it should be pointed out that if a transformed distribution $\tilde{f}_\perp$ is defined such that

$$\tilde{f}_\perp d^2x_\perp d^2\tilde{x}_\perp = f_\perp d^2x_\perp d^2x'_\perp,$$

then the Jacobian of the transformation (A5) $d^2\tilde{x}_\perp d^2\tilde{x}'_\perp = (\gamma_b\beta_b)^2 d^2x_\perp d^2x'_\perp$, and consequently $\tilde{f}_\perp$ is simply related to the beam distribution $f_\perp$ by

$$\tilde{f}_\perp = \frac{1}{(\gamma_b\beta_b)^2} f_\perp.$$  \hspace{1cm} (A12)

If one naturally defines a charge-density for the transformed distribution as

$$\tilde{\rho} = q \int d^2\tilde{x}_\perp \tilde{f}_\perp,$$

then the regular charge distribution $\rho = q \int d^2x'_\perp f_\perp$ is related to $\tilde{\rho}$ by

$$\tilde{\rho} = \frac{1}{\gamma_b\beta_b} \rho.$$  \hspace{1cm} (A14)

and the transformation of the Poisson equation (9) is

$$\left( \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right) \tilde{\phi} = -\frac{\rho}{\varepsilon_0} = -\frac{\rho}{\gamma_b\beta_b\varepsilon_0}.$$  \hspace{1cm} (A15)

The additional factor of $1/(\gamma_b\beta_b)$ is an expression of the weakening of transverse space-charge effects with acceleration and must be treated with care to establish the proper correspondences.

**APPENDIX B: LINEAR-FORCE COURANT-SNYDER INVARIANTS**

An $x$-plane particle orbit within a KV beam is described by the Hill’s equation\[30–32, 36, 63\]

$$x''(s) + \kappa_x(s)x(s) - \frac{2Qx(s)}{[r_x(s) + r_y(s)]r_x(s)} = 0.$$  \hspace{1cm} (B1)

For $Q = 0$ this equation also describes an $x$-plane orbit of a single-particle moving in the linear applied-focusing fields of a lattice. In a phase-amplitude resolution of the particle orbit we take

$$x = A_x \cos \psi_x,$$

where $A_x$ and $\psi_x$ denote $s$-varying amplitude and phase functions. Without loss of generality, $A_x$ and $\psi_x$ can be taken to satisfy $2A_x \psi'_x + A_x \psi''_x = 0$, or equivalently,

$$\psi'_x = \frac{\text{const}}{A_x^2}.$$  \hspace{1cm} (B3)

The amplitude is set to be $A_x = A_x r_x$, where $A_x$ is a positive dimensionless constant. We can then take const $= A_x^2 \varepsilon_x$ in Eq. (B3) without restrictions on the generality of the solution. Then the equation of motion (B1) becomes

$$A_x \left[ r_x'' + \kappa_x r_x - \frac{2Q}{r_x + r_y} - \frac{\varepsilon_x^2}{r_x^2} \right] = 0,$$

$$\psi'_x = \frac{\varepsilon_x}{r_x^2}.$$  \hspace{1cm} (B4)

The amplitude equation is satisfied for $A_x \neq 0$ if the $r_j$ ($j = x, y$) satisfy the KV envelope equation (21). Note that the rate of phase-advance, $\psi'_x = \varepsilon_x/r_x^2$, is independent of relative particle oscillation amplitude $A_x$. This phase
Adding the square of these equations, we obtain the Courant-Snyder invariant

$$\sigma_x = \psi_x(s_i + L_p) - \psi_x(s_i) = \varepsilon_x \int_{s_i}^{s_i + L_p} ds \frac{r_x}{r_x^2}.$$  \hfill (B5)

If the focusing lattice is periodic with period $L_p$, and the envelope $r_j$ is matched, then the “depressed” phase-advance $\sigma_x$ [see Eq. (25)] is independent of $s_i$. Using $A_x = A_r r_x$ and $\psi_x' = \varepsilon_x/r_x^2$, we have

$$\frac{x}{r_x} = A_x \cos \psi_x,$$

$$\frac{r_x x' - r_x' x}{\varepsilon_x} = A_x \sin \psi_x.$$ \hfill (B6)

Adding the square of these equations, we obtain the Courant-Snyder invariant

$$\left(\frac{x}{r_x}\right)^2 + \left(\frac{r_x x' - r_x' x}{\varepsilon_x}\right)^2 = A_x^2 = \text{const}.$$ \hfill (B7)

An analogous invariant holds in the $y$-plane.

The $x$-$x'$ phase-space area enclosed by the ellipse defined by the Courant-Snyder invariant (B7) is $\pi \varepsilon_x A_x$. A particle at the edge of the beam in phase-space will have amplitude $A_x = 1$, showing that $\pi \varepsilon_x$ is the maximum phase-space area enclosed by particles in the coasting beam. A statistical average of Eq. (B7) shows that $\langle A_x^2 \rangle = 1/2$ for consistency with the requirement that the statistical emittance of a KV beam satisfy $\varepsilon_x^2 = 16 \langle x^2 \rangle \langle x'^2 \rangle - \langle x x' \rangle^2$. For the KV distribution, $\varepsilon_x$ can be interpreted as the maximum single-particle emittance and a statistical edge measure of the rms-edge emittance (i.e., $\varepsilon_x = 4 \varepsilon_{x,\text{rms}}$). Note that the KV distribution (16) is a delta-function of $x$- and $y$-plane Courant-Snyder invariants that generates the required uniform-density elliptical beam required for self-consistency. The initial particle distributions defined in Sec. III D are based on linear-field Courant-Snyder invariants.

In the limit of zero space-charge, $Q = 0$, the Courant-Snyder invariant (B7) reduces to a form familiar from conventional accelerator physics of a single-particle oscillating in linear applied-fields[91]. In this case it is conventional to employ alternative, positive-definite amplitude functions $\beta_{0j}(s)$ (or alternatively, $w_{0j} = \beta_{0j}^2$) that are related to the $Q = 0$ envelope functions $r_j \equiv r_{0j}$ by

$$r_{0j} = \sqrt{\varepsilon_j} w_{0j} = \sqrt{\varepsilon_j} \beta_{0j}.$$ \hfill (B8)

The function $\beta_{0j}$ is called the betatron function, and for periodic lattices, is employed analogously to a defined special function that characterizes the applied-focusing properties of the lattice.

The Courant-Snyder invariant can be applied to improve the understanding of the pseudo-equilibrium initial distributions defined in Sec. IV. Using the transformation (87) in the Courant-Snyder invariant (B7), we obtain

$$\left(\frac{x}{r_b}\right)^2 + \left(\frac{r_b x' - r_b' x}{\varepsilon_b}\right)^2 = \text{const},$$ \hfill (B9)

where $r_b$ and $\varepsilon_b$ are the envelope radius and emittance of an rms-equivalent, matched KV beam in a continuous-focusing channel. Adding the analogous $y$-plane invariant then shows that

$$2 \frac{r_b^2}{\varepsilon_b^2} \left[ \frac{1}{2} x_1^2 + \frac{\varepsilon_b^2}{2r_b^2} x_1^2 \right] = A_x^2 + A_y^2 = \text{const}.$$ \hfill (B10)

For a matched KV equilibrium beam in a continuous-focusing channel, it is straightforward to show that the transverse beam Hamiltonian $H_\perp = \frac{1}{2} x_1^2 + \frac{k_b^2}{2} x_1^2 + q \phi/(m r_b^2 \beta_b^2 c^2)$ can be expressed as $H_\perp = \frac{1}{2} x_1^2 + \frac{k_b^2}{2} x_1^2$ [see Eq. (45)], giving

$$2 \frac{r_b^2}{\varepsilon_b^2} H_\perp = A_x^2 + A_y^2 = \text{const}.$$ \hfill (B11)

This shows that the composite Courant-Snyder invariant $A_x^2 + A_y^2$ is proportional to $H_\perp$ for the equivalent continuous-focusing channel. Therefore, the transforms applied to generate the pseudo-equilibrium distributions from a continuous-focusing equilibrium distribution preserve linear-field Courant-Snyder invariants appropriate for the non-continuous lattice. The transformations fail to produce an exact equilibrium because the self-fields are not linear for general (non-KV) continuous equilibrium distributions employed. For strong space-charge, the approximation of replacing the actual nonlinear space-charge field with an rms-equivalent beam linear-field is expected to be worse for particles near the edge of the beam.
APPENDIX C: RMS-EQUIVALENCY AND PROJECTIONS OF THE DISTRIBUTIONS IN SEC. III D

For a distribution to be rms-eqivalent with a KV distribution described by the envelope radii \( r_j \) (\( j = x, y \)), the envelope angles \( r_j' \), and the rms-edge emittances \( \varepsilon_j \), it follows from Eqs. (23) and (24) that the nonzero second-order moments of the distribution must satisfy

\[
\langle x^2 \rangle_L = \frac{r_x^2}{4}, \quad \langle xx' \rangle_L = \frac{r_x r'_x}{4}, \quad \langle x'2 \rangle_L = \frac{r_x^2}{4} + \frac{\varepsilon_x^2}{4r_x^2}.
\]  
(C1)

Here, we have expressed the \( x \)-plane equations and \( \langle \cdots \rangle_L = \int d^2x \int d^2x' \cdots f_L / \int d^2x \int d^2x' f_L \). Analogous equations hold in the \( y \)-plane both here and in subsequent equations. All second-order cross-moments must vanish (e.g., \( \langle xy \rangle_L = 0 \)).

To analyze constraints that rms-equivallency places on the class of linear-field Courant-Snyder invariant (LCS) distributions defined by Eqs. (60)–(64), it is convenient to employ canonical transformations[30] by taking

\[
X \equiv \sqrt{\frac{\varepsilon_x x}{r_x}}, \quad \hat{X} \equiv \frac{\sqrt{\varepsilon_x x}}{r_x} \left( \frac{r_x x' - r'_x x}{\varepsilon_x} \right),
\]  
(C2)

with inverse transform

\[
x = \frac{r_x}{\sqrt{\varepsilon_x}} X, \quad x' = \frac{\sqrt{\varepsilon_x}}{r_x} \hat{X} + \frac{r'_x}{\sqrt{\varepsilon_x}} X.
\]  
(C3)

Phase-space area elements transform as

\[
d^2x_L = dx \otimes dy = \frac{r_x r_y}{\sqrt{\varepsilon_x \varepsilon_y}} dX \otimes dY, \quad d^2x'_L = dx' \otimes dy' = \frac{\sqrt{\varepsilon_x \varepsilon_y}}{r_x r_y} d\hat{X} \otimes d\hat{Y},
\]  
(C4)

with

\[
d^2x_L d^2x'_L = dx \otimes dy \otimes dx' \otimes dy' = dX \otimes dY \otimes d\hat{X} \otimes d\hat{Y},
\]  
(C5)

reflecting the local phase-space invariance of a canonical transform[97]. Using these canonical transforms it is straightforward to show that the rms-eqivalency requirements in Eq. (C1) can be expressed as

\[
\langle X^2 \rangle_L = \langle \hat{X}^2 \rangle_L = \frac{\varepsilon_x}{2}, \quad \langle X \hat{X} \rangle_L = 0,
\]  
(C6)

and the linear-field Courant-Snyder invariant \( A^2 \) in Eq. (61) becomes

\[
A^2 = \frac{1}{\varepsilon_x} (X^2 + \hat{X}^2) + \frac{1}{\varepsilon_y} (Y^2 + \hat{Y}^2),
\]  
(C7)

thereby simplifying the expression of the LCS distribution (60) to

\[
 f_L(A^2) = \frac{\lambda}{q} f \left( \frac{X^2 + \hat{X}^2}{\varepsilon_x} + \frac{Y^2 + \hat{Y}^2}{\varepsilon_y} \right).
\]  
(C8)

Employing Eqs. (C5) and (C8), it follows by symmetry that \( \langle X \hat{X} \rangle_L = 0 \) is satisfied independent of the form of the function \( f \) used in the distribution definition (C8). Some straightforward manipulation using these equations then shows that \( \langle X^2 \rangle_L = \langle \hat{X}^2 \rangle_L = \varepsilon_x/2 \) is satisfied if the function \( f \) satisfies

\[
\frac{\int_0^\infty dU \int_0^\infty d\tilde{U} U f(U + \tilde{U})}{\int_0^\infty dU \int_0^\infty d\tilde{U} f(U + \tilde{U})} = \frac{1}{2}.
\]  
(C9)

Here, \( U \equiv X^2/\varepsilon_x + Y^2/\varepsilon_y \) and \( \tilde{U} \equiv \hat{X}^2/\varepsilon_x + \hat{Y}^2/\varepsilon_y \). Denoting

\[
G(U) \equiv \int_0^\infty d\tilde{U} f(\tilde{U}),
\]  
(C10)
the constraint in Eq. (C9) can be equivalently expressed as

$$\frac{\int_0^\infty dU \ U G(U)}{\int_0^\infty dU \ G(U)} = \frac{1}{2}. \quad (C11)$$

This shows that the moment constraints (C1) required for rms-equivalency are automatically satisfied for LCS distributions defined by Eqs. (60)–(61) regardless of the (physical) values of $r_j$, $r'_j$, and $\varepsilon_j$ and the specific form of the choice of function $f$.

Projections of the LCS distributions can be more easily calculated using the canonical transforms in Eqs. (C2)–(C5). For example, the $x$–$y$ density projection reduces to

$$n = \int d^2 x' f_\perp = \frac{\lambda \sqrt{\varepsilon_x \varepsilon_y}}{q} \int dX \int dY f \left( \frac{X^2 + \dot{X}^2}{\varepsilon_x} + \frac{Y^2 + \dot{Y}^2}{\varepsilon_y} \right)$$

$$= \frac{\pi \lambda \varepsilon_x \varepsilon_y}{q} \int_\infty^\infty dU f(U), \quad (C12)$$

where $\xi^2 \equiv x^2/r_x^2 + y^2/r_y^2$. Similarly, using

$$dy \otimes dy' = dY \otimes d\dot{Y}, \quad (C13)$$

the canonical transforms can be applied to calculate the $x$–$x'$ phase-space projection as

$$\int dy \int dy' f_\perp = \frac{\lambda}{q} \int dY \int d\dot{Y} f \left( \frac{X^2 + \dot{X}^2}{\varepsilon_x} + \frac{Y^2 + \dot{Y}^2}{\varepsilon_y} \right)$$

$$= \frac{\pi \lambda \varepsilon_y}{q} \int_\infty^A dU f(U), \quad (C14)$$

where $A_x^2 \equiv (x/r_x)^2 + (r_x x' - r'_x x)^2/\varepsilon_x^2$. Further simplifications to Eqs. (C12) and (C14) can be made for specific choices of $f$ (see Table II).

**APPENDIX D: CONTINUOUS-FOCUSING WATERBAG EQUILIBRIUM DISTRIBUTION**

A thorough treatment of the waterbag equilibrium has been presented by Reiser[31] and others[32, 62–64, 98]. Here we review and extend analysis of the waterbag equilibrium within the present framework to facilitate generation of Vlasov simulation loads formulated with standard inputs for accelerator simulations. For a waterbag equilibrium distribution in continuous-focusing, we take

$$f_\perp (H_\perp) = f_0 \Theta(H_b - H_\perp). \quad (D1)$$

Here, $\Theta(x)$ is a unit-step function [see Eq. (57)], $f_0 = \text{const} > 0$ is the distribution normalization factor, and $H_b = \text{const}$ is the value of the Hamiltonian $H_\perp$ at the physical beam edge at radius $r = r_e$, i.e.,

$$H_\perp |_{r = r_e} = H_b. \quad (D2)$$

The waterbag distribution expresses that all transverse particle energies out to the beam edge have uniform probability, which gives rise to the name “waterbag” motivated by analogy to an incompressible fluid confined within a membrane boundary. The sharp beam edge in phase-space associated with the step-function definition of the distribution generates a simple, highly idealized model conducive to analytical calculations. Because $\partial f_\perp (H_\perp) / \partial H_\perp = -f_0 \delta (H_b - H_\perp) \leq 0$, the waterbag distribution is stable to all perturbations within the Vlasov model[30, 32].

Using the formulation developed in Sec. IIIB, we take $H_\perp = x^2/2 + \psi$ with $\psi = k^2 \beta_0 y^2/2 + q\phi/(m \gamma_b^3 \beta_0^2 c^2)$, and calculate the radial beam density $n = \int d^2 x'_\perp f_\perp$ using Eqs. (36) and (D1) to be

$$n(r) = 2\pi f_0 \left\{ \begin{array}{ll} H_b - \psi(r), & \psi < H_b, \\ 0, & \psi > H_b. \end{array} \right. \quad (D3)$$
Note that the density falls smoothly to zero at the physical beam edge [i.e., \( n(r = r_e) = 0 \)]. The physical edge radius \( r_e \) is generally distinct from the rms-edge radius \( r_b = \sqrt{\langle r^2 \rangle} \) with \( r_e > r_b \). Using Eq. (D3), the transformed Poisson equation (37) for \( \psi \) can be expressed within the beam \((r < r_e)\) as

\[
\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial \psi}{\partial r} \right) - k_0^2 \psi = 2k_{\beta 0}^2 - k_0^2 H_b, \tag{D4}
\]

where

\[
k_0^2 = \frac{2\pi q^2 f_0}{\epsilon_0 m^2 \beta_b^2 \epsilon^2} = \text{const.} \tag{D5}
\]

Equation (D4) is a modified Bessel function equation of order zero [99]. The solution \( \psi \) of this equation that is regular as \( r \to 0 \) and satisfies \( \psi(r = r_e) = H_b \) is given within the beam by

\[
\psi(r) = H_b - 2k_{\beta 0}^2 \frac{k_0^2}{k_0^4} \left[ 1 - \frac{I_0(k_0 r)}{I_0(k_0 r_e)} \right], \tag{D6}
\]

where \( I_\ell(x) \) is the modified Bessel function of order \( \ell \). Using this result, Eq. (D3) for the density becomes

\[
n(r) = 4\pi f_0 \frac{k_{\beta 0}^2}{k_0^4} \left[ 1 - \frac{I_0(k_0 r)}{I_0(k_0 r_e)} \right]
\]

\[
= \frac{2\epsilon_0 m^2 \beta_b^2 \epsilon^2 k_{\beta 0}^2}{q^2} \left[ 1 - \frac{I_0(k_0 r)}{I_0(k_0 r_e)} \right] \tag{D7}
\]

within the beam. Similarly, the \( x \)-plane kinetic temperature \( T_x = \langle x'^2 \rangle_{x'_\perp} \) is calculated, using Eq. (38) and previous results, to be

\[
T_x(r) = \frac{k_{\beta 0}^2}{k_0^4} \left[ 1 - \frac{I_0(k_0 r)}{I_0(k_0 r_e)} \right] \tag{D8}
\]

within the beam. Comparing Eq. (D7) and Eq. (D8), note that \( T_x(r) \propto n(r) \). This proportionality between \( T_x \) and \( n \) is a consequence of the waterbag equilibrium choice for \( f_\perp(H_\perp) \), and is not a general result for continuous-focusing equilibria.

In Fig. 10 the normalized waterbag density profile is plotted as a function of \( k_0 r \) for characteristic values of \( k_0 r_e \). Note that as \( k_0 r_e \) increases, the density profile (and the temperature profile with \( T_x \propto n \)) become increasingly flat within the core of the beam, with \( r \ll r_e \).

FIG. 10: For a waterbag equilibrium, the scaled density profile \( n(r)/\{4\pi f_0 (k_{\beta 0}^2/k_0^4)[1 - 1/I_0(k_0 r_e)]\} \) is plotted versus the scaled radial coordinate \( k_0 r \), calculated from Eq. (D7) for the indicated values of \( k_0 r_e \).

It can be useful to employ \( H_\perp = \frac{1}{2} x'^2_\perp + \psi \) [see Eq. (35)] and Eq. (D6) for \( \psi \) to explicitly calculate the waterbag distribution as

\[
f_\perp(x_\perp, x'_\perp) = f_0 \Theta \left( \frac{k_{\beta 0}^2}{k_0^4} \left[ 1 - \frac{I_0(k_0 r)}{I_0(k_0 r_e)} \right] - \frac{1}{2} x'^2_\perp \right). \tag{D9}
\]
Note that $H_b$ has been eliminated in Eq. (D9), and the distribution is expressed in terms of normalization factor $f_0$, the scaled edge radius $k_0 r_e$, and $k_{30}/k_0$.

To use the formulation above effectively, distribution parameters should be cast in terms of usual quantities associated with accelerator physics as discussed in Sec. III B. First, the beam line-charge can be calculated using $\lambda = 2\pi q \int_0^\infty dr \, n(r)$ and Eq. (D7) to show that

$$\lambda = 4\pi^2 q f_0 \frac{k_{30}^2}{k_0^2} \frac{r_e}{7} \left[ 1 - \frac{2}{k_0 r_e} \frac{I_1(k_0 r_e)}{I_0(k_0 r_e)} \right] \tag{D10}$$

Here we have employed the modified Bessel function identities\[99\]

$$\frac{d}{dx} \left[ x^\ell I_\ell(x) \right] = x^\ell I_{\ell-1}(x),$$

$$-\frac{2\ell}{x} I_\ell(x) = I_{\ell+1}(x) - I_{\ell-1}(x),$$

with $\ell$ an integer, to simplify the integrals in the calculation of $\lambda$. Similarly, the statistical rms-beam envelope given by $r_b = \sqrt{2\langle r^2 \rangle_{\perp}}$ with $\langle r^2 \rangle_{\perp} = \int_0^\infty dr \, r^2 n(r)/f_0 d^2 r n(r)$ can be explicitly calculated using Eq. (D7) [or equivalently, using Eq. (40)] to be

$$\left( \frac{r_b}{r_e} \right)^2 = \frac{I_0(k_0 r_e)}{I_2(k_0 r_e)} - \frac{4}{(k_0 r_e)^2} \left[ 2 + \frac{I_3(k_0 r_e)}{I_2(k_0 r_e)} \right]. \tag{D11}$$

From Eqs. (D5) and (D10), the perveance $Q = q\lambda/(2\pi\varepsilon_0 m \gamma_0^3 \beta_0^2 c^2)$ is conveniently expressed as

$$Q = \langle k_{30} r_e \rangle^2 I_2(k_0 r_e). \tag{D12}$$

Then Eqs. (D11) and (D12) can be combined to obtain the constraint equation

$$\frac{k_{30}^2 \beta_b^2}{Q} = \frac{I_0^2(k_0 r_e)}{I_2^2(k_0 r_e)} - \frac{4}{(k_0 r_e)^2} \left[ 2 \frac{I_0(k_0 r_e)}{I_2(k_0 r_e)} + \frac{I_0(k_0 r_e) I_3(k_0 r_e)}{I_2^2(k_0 r_e)} \right], \tag{D13}$$

which relates the dimensionless factor $k_0 r_e$ in terms of the dimensionless ratio of beam physics parameters $k_{30}^2 \beta_b^2 / Q$. Using Eq. (47), $k_{30}^2 \beta_b^2 / Q$ [or $k_0 r_e$ using Eq. (D13)] can be directly related to the rms-equivalent beam measure of relative space-charge strength $\sigma/\sigma_0$ as

$$\frac{k_{30}^2 \beta_b^2}{Q} = \frac{1}{1 - (\sigma/\sigma_0)^2}. \tag{D14}$$

Alternatively, the dimensionless self-field parameter $s_b$ defined in Eq. (48) can be related to $k_0 r_e$ from

$$s_b = \frac{\hat{\omega}_p^2}{2 \gamma_0^3 \beta_0^2 c^2 k_{30}^2} = 1 - \frac{1}{I_0(k_0 r_e)}. \tag{D15}$$

Here, $\hat{\omega}_p = \sqrt{\varepsilon_0 n/(\varepsilon_0 m)}$ is the plasma frequency defined from the peak, on-axis beam density $n = n(r = 0)$. For specified $Q$ the ratio of $k_0/k_{30}$ can be calculated from Eqs. (D12) and $k_0 r_e$ as

$$\frac{k_{30}}{k_0} = \frac{1}{(k_0 r_e)\sqrt{Q I_0(k_0 r_e) / I_2(k_0 r_e)}}. \tag{D16}$$

The matched-beam envelope constraint [see Eq. (39)]

$$k_{30}^2 \beta_b^2 - \frac{Q}{r_b} - \frac{\varepsilon_b^2}{r_b^2} = 0 \tag{D17}$$
can be employed in the constraint equation (D13) to eliminate either $k^2_{3b}$, $r_b$, or $Q$ occurring in $k^2_{3b}r_b^2/Q$ in terms of the emittance $\varepsilon_b$ to affect various parametrization choices.

The nonlinear constraint equation (D13) must, in general, be solved numerically to specify the needed value of $k_0 r_e$. Using Eqs. (D13) and (D14), $k_0 r_e$ can be regarded as a function of the rms-equivalent beam tune depression $\sigma/\sigma_0$. These equations are solved numerically to plot $k_0 r_e$ as a function of $\sigma/\sigma_0$ in Fig. 11. Because $k_0 r_e$ is a one-to-one function of $\sigma/\sigma_0$, the relative space-charge strength can be regarded as uniquely determining $k_0 r_e$. Figure 11 illustrates the wide range of characteristic values of $k_0 r_e$ obtainable as the relative space-charge strength is varied.

From the envelope equation, note that $k^2_{3b}r_b^2/Q = 1 + \varepsilon_b^2/(Qr_b^2) > 1$. Analysis of Eq. (D13) shows that $k^2_{3b}r_b^2/Q$ is a monotonic decreasing function of $k_0 r_e$, with $\lim_{k_0 r_e \to 0} k^2_{3b}r_b^2/Q \to \infty$ and $\lim_{k_0 r_e \to \infty} k^2_{3b}r_b^2/Q = 1$. Therefore, a unique value of $k_0 r_e \in (0, \infty)$ exists for any equilibrium with finite space-charge ($Q \neq 0$). Analytical solution of the constraint equation (D13) is possible in the limit of small and large values of $k_0 r_e$. Using the expansion[99]

$$I_\ell(x) = \sum_{k=0}^{\infty} \frac{(x/2)^{\ell+2k}}{k!(\ell+k)!}$$

for $|x| \ll 1$, we obtain to leading-order

$$k_0 r_e \simeq \frac{4}{\sqrt{3(k^2_{3b}r_b^2/Q - 17/18)}}$$

(D18)

for values of $k^2_{3b}r_b^2/Q$ sufficiently large to produce small $k_0 r_e$. This limit of small $k^2_{3b}r_b^2/Q$ corresponds to weak space-charge forces relative to applied-focusing forces ($\sigma/\sigma_0 \sim 1$) and Eqs. (D6) and (D7) for $n(r)$ can be approximated in this regime as

$$n(r) \simeq \pi \varepsilon_0 k^2_{3b}(r_e^2 - r^2)$$

(D19)

within the beam. Similar parabolic approximations follow immediately for $\psi$ and $T_x$ in this limit. Using the expansion[99]

$$I_\ell(x) = \frac{e^x}{\sqrt{2\pi x}} \left[ 1 + \frac{(-1)^l(4\ell^2 - 1^2)}{1!(8x)^l} + \frac{(-1)^l(4\ell^2 - 1^2)(4\ell^2 - 3^2)}{2!(8x)^l} \right] \ldots$$

for $x \gg \ell$, the constraint equation (D13) can be approximated to leading-order as

$$k_0 r_e \simeq \frac{2}{\sqrt{k^2_{3b}r_b^2/Q - 1}}$$

(D20)

for values of $k^2_{3b}r_b^2/Q > 1$ sufficiently close to unity to produce large $k_0 r_e$. The large-$k_0 r_e$ regime corresponds to strong space-charge depression with $\sigma/\sigma_0$ small. Simplified expressions for the density profile valid within the full radial range of the beam core are more difficult to derive in this case. For general space-charge strengths, the limiting solutions in Eqs. (D18) and (D20) can be employed to seed numerical solutions of the constraint equation (D13) using conventional root-finding techniques[89].

FIG. 11: Waterbag equilibrium parameter $k_0 r_e$ versus rms-equivalent beam tune depression $\sigma/\sigma_0$ as calculated from Eqs. (D13) and (D14).
Although the envelope equation (39) can be applied to calculate the beam rms-edge emittance \( \varepsilon_b \) in terms of \( k_{\beta 0}^2, r_b \), and \( Q \), it can be useful in some circumstances to calculate \( \varepsilon_b = \varepsilon_j \) explicitly for the waterbag distribution function (D1). From Eq. (42) and Eq. (D1), \( \varepsilon_b^2 = 2r_b^2 \left( x_{y}^2 \right)_{\perp} \) can be calculated to be

\[
\varepsilon_b^2 = \frac{16\pi^2 q f_0 \nu_b^2}{\lambda} \left[ \frac{H_{b}^2 r_e^2}{4} - H_{b} \int_{0}^{r_e} dr r \psi + \frac{1}{2} \int_{0}^{r_e} dr r \psi^2 \right].
\]

Use of Eqs. (D6) and (D10) in this result leads to

\[
\varepsilon_b^2 = 4r_b^2 k_{\beta 0}^2 \left[ \frac{2 I_0(k_0 r_e)}{I_2(k_0 r_e)} - \frac{I_1(k_0 r_e)}{I_2(k_0 r_e)} \right].
\] (D21)

To better understand properties of the waterbag equilibrium, we employ Eqs. (D11)–(D17) to plot the radial density profile and the phase-space boundary of the distribution in Fig. 12 for fixed applied-focusing strength \( (k_{\beta 0}^2 = \text{const}) \) and fixed beam perveance \( (Q = \text{const}) \) as the relative space-charge strength \( (\sigma/\sigma_0) \) is varied. In Fig. 12(a) the scaled radial density profile is plotted. For the waterbag equilibrium the temperature profile is proportional to the density profile \( [i.e., T_x \propto n, \text{see Eqs. (D7) and (D8)}] \), and therefore Fig. 12(a) also serves to illustrate the beam radial temperature profile. The boundary edge of the waterbag equilibrium distribution in \( x_{\perp} \)-\( x'_{\perp} \) phase-space is shown in Fig. 12(b). This \( f_\perp = 0 \) boundary is calculated as the maximum value of \( x'_{\perp} \) as a function of \( r \) from Eq. (D9) to be

\[
\text{Max}(x'_{\perp}) = 2k_{\beta 0} k_0 r_e \left[ 1 - \frac{I_0(k_0 r)}{I_0(k_0 r_e)} \right]^{1/2}
\] (D22)

within the beam. The distribution \( f_\perp \) is uniformly filled within the outer edge. Various dimensionless parameters for the equilibria in Fig. 12 are given in Table III. Note that for strong space-charge (small \( \sigma/\sigma_0 \)) the waterbag equilibrium density profile becomes very flat deep within in the core \( (r \ll r_e) \) due to Debye screening effects associated with the interaction of the applied-focusing and space-charge forces\[30, 100\]. Near the edge \( (r \lesssim r_e) \) the applied-focusing forces start to dominate the self-field forces and the density decreases rapidly to zero with a characteristic (modified Bessel function) fall-off associated with the waterbag equilibrium choice. For weak relative space-charge forces \( (\sigma/\sigma_0 \sim 1) \), the density profile approaches the parabolic limiting form in Eq. (D19), and the phase-space boundary becomes elliptical \( [i.e., \text{Eq. (D22)} \text{is approximated by } \text{Max}(x'_{\perp})^2 + k_{\beta 0}^2 r_e^2 = k_{\beta 0}^2 r_e^2] \). For large relative space-charge intensity \( (\sigma/\sigma_0 \ll 1) \), the phase-space boundary of the uniform core distribution becomes more rectangular, indicating nearly force-free motion deep within the beam core until particles enter the edge-region where a strong nonlinear force transition effectively reflects the particles. From Table III, note that small values of \( \sigma/\sigma_0 \) correspond to values of the self-field parameter \( s_b \) that are extremely close to \( s_b = 1 \). Thus, the self-field parameter is insensitive relative to \( k_0 r_e \) to employ to specify scaled intense-beam waterbag equilibria with high space-charge intensity.
FIG. 12: Waterbag equilibrium distribution in continuous-focusing channel for fixed focusing-field strength ($k_{\beta 0}^2 = \text{const}$) and perveance $Q = 10^{-4}$ with (rms-equivalent beam measure) relative space-charge strengths $\sigma/\sigma_0 = 0.9, 0.8, \cdots, 0.1$. In a) the scaled density profile $\left[q^2/(2m\epsilon_0^2 e\gamma(r^3 k_{\beta 0}^2))n(r)\right]$ is plotted versus the dimensionless radial coordinate $k_{\beta 0}r$, and in b) the distribution edge ($f_\perp = 0$ curve) in $x_\perp-x_\perp'$ phase-space is plotted as a function of $k_{\beta 0}r$ and $|x_\perp'|$. Values of $\sigma/\sigma_0$ correspond to the dimensionless equilibrium parameters in Table III.

TABLE III: Dimensionless waterbag equilibrium parameters in Fig. 12 calculated for specified $\sigma/\sigma_0$. The values of $k_0/k_{\beta 0}$ and $k_{\beta 0}\varepsilon_b$ are evaluated for $Q = 10^{-4}$, and all other quantities are independent of $Q$.

To load the waterbag equilibrium distribution in either direct-Vlasov or PIC simulations, the general framework presented in Sec. III B can be applied. For PIC loading of the waterbag distribution, the radial probability transform (51) for loading particle coordinates $x_\perp$ can be expressed in the reduced form

$$\frac{r}{r_e} \left[ \frac{r}{r_e} \frac{I_0(k_0 r_e)}{I_2(k_0 r_e)} - \frac{1}{k_0 r_e} \frac{I_1(k_0 r)}{I_2(k_0 r_e)} \right] = \hat{u}_r. \quad (D23)$$

Here, $\hat{u}_r \in [0, 1)$ is a uniformly-distributed random number. This equation must, in general, be solved numerically for $r(\hat{u}_r)$ to specify particle coordinates using Eq. (52). Values can be saved on a radial grid in $r \in [0, r_e]$, and interpolation applied to efficiently load many particles. For loading the particle angles $x'_\perp$, the probability transform (53) can be greatly simplified by exploiting the structure of the waterbag distribution. With particle radii $r = |x_\perp|$ specified, the particle angles $|x'_\perp|$ are uniformly distributed in $U = \frac{1}{2} x'_\perp^2$ from $U = 0$ to a maximum value consistent with Eq. (D22).
leading to

\[ U(\hat{u}_v) = 2k_0^2 \frac{\hat{k}_0^2}{k_0^2} \left[ 1 - \frac{I_0(k_0r)}{I_0(k_0r_e)} \right] \hat{u}_v. \] (D24)

Here, \( \hat{u}_v \in [0, 1] \) is a uniformly-distributed random number. Particle angles are set using this value of \( U(\hat{u}_v) \) in Eq. (54).

**APPENDIX E: CONTINUOUS-FOCUSING PARABOLIC EQUILIBRIUM DISTRIBUTION**

For a parabolic equilibrium distribution in continuous-focusing, we take

\[ f_\perp(H_\perp) = f_0(H_b - H_\perp)\Theta(H_b - H_\perp), \] (E1)

where \( \Theta(x) \) is a unit-step function [see Eq. (57)], \( f_0 = \text{const} > 0 \) is the distribution normalization factor, and \( H_b = \text{const} \) is the value of the Hamiltonian \( H_\perp \) at the physical beam edge at radius \( r = r_e \), i.e.,

\[ H_\perp|_{r=r_e} = H_b. \] (E2)

The parabolic distribution has linearly decreasing particle probabilities with increasing transverse particle energy out to a sharp beam edge where the probability is zero. This distribution is named “parabolic” because at fixed \( x_\perp \), the probability decreases parabolically with increasing \( x_\perp^2 \) due to the \( \frac{1}{2}x_\perp^2 \) dependence of \( H_\perp \) on \( x_\perp^2 \). The parabolic distribution coarsely reflects what one might expect on physical grounds — that probabilities fall off towards the edge of the beam in a continuous manner, and may in this sense represent a lesser degree of idealization than the waterbag distribution [see Sec. D].

Using the formulation developed in Sec. III B, we take \( H_\perp = x_\perp^2/2 + \psi \) with \( \psi = k_0^2r^2/2 + q\phi/(m\gamma_0^3\beta_0^2c^2) \) and calculate the radial beam density profile \( n(r) = \int d^2x_\perp f_\perp \) from Eqs. (E1) and (36). This gives

\[ n(r) = \pi f_0 \begin{cases} 
[H_b - \psi(r)]^2, & \psi < H_b, \\
0, & \psi > H_b.
\end{cases} \] (E3)

Using Eq. (E3), the transformed Poisson equation (37) can be conveniently expressed within the beam \( (r < r_e) \) as

\[ \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial \psi}{\partial r} \right) + \frac{K}{2}(H_b - \psi)^2 = 2k_0^2r_e^2. \] (E4)

Here,

\[ K = \frac{2\pi q^2 f_0 H_b r_e^2}{\epsilon_0 m\gamma_0^3 \beta_0^2 c^2} = \text{const} \] (E5)

is a dimensionless constant. Equation (E4) can be integrated subject to

\[ \psi(r = r_e) = H_b, \]
\[ \frac{\partial \psi}{\partial r}\bigg|_{r=0} = 0, \]
\[ \frac{\partial \psi}{\partial r}\bigg|_{r=r_e} = \frac{k_0^2r_e - Q}{r_e}. \] (E6)

Here, \( \psi(r = r_e) = H_b \) follows from Eq. (E2), the derivative condition on \( \psi \) at \( r = 0 \) follows from the structure of Eq. (E4), and the derivative condition on \( \psi \) at \( r = r_e \) is readily derived from a direct integration on the equilibrium Poisson equation (33) to show that \( \partial \phi/\partial r|_{r=r_e} = -\lambda/(2\pi q_0r_e) \) and employing the definition of the perveance \( Q = q\lambda/(2\pi q_0m\gamma_0^3 \beta_0^2 c^2) \) = const.

Eq. (E4) for \( \psi \) is highly nonlinear and must be numerically integrated subject to the conditions in Eq. (E6). The integration can be carried out inward from \( r = r_e \) and subject to the two “initial” conditions in Eq. (E6) at \( r = r_e \), i.e., \( \psi(r = r_e) = H_b \) and \( \frac{\partial \psi}{\partial r}|_{r=r_e} = k_0^2r_e - Q/r_e \). Only specific parameters will be consistent with the derivative condition \( \frac{\partial \psi}{\partial r}|_{r=0} = 0 \) in Eq. (E6) necessary for a physical solution. This boundary condition can in this sense be employed as a constraint to eliminate one free parameter. Careful analysis of Eqs. (E4) and (E6) show that simple
rescalings result in a final system with three free parameters, one of which can be regarded as eliminated in enforcing boundary conditions. Ultimate specification of the solution in terms of usual quantities associated with accelerator physics as discussed in Sec. III B will, in general, become complicated to enforce even in numerical solution.

Fortunately, a more convenient alternative formulation can be derived as follows. Within the beam \( (r < r_e) \), Eq. (E3) can used to relate \( \psi \) to \( n \) by

\[
\psi = H_b \left( 1 - \sqrt{\frac{n}{\pi f_0 H_b^2}} \right) .
\]

(E7)

This result, together with a simple variable rescaling

\[
r \equiv r_s \rho, \\
n \equiv \hat{n} N,
\]

(E8)

where \( r_s > 0 \) is a scale radius to be determined, and \( \hat{n} = n(r = 0) > 0 \) is the on-axis density \([N(\rho = 0) = 1]\), can then be applied to express Eq. (E4) to give

\[
N \frac{\partial^2 N}{\partial \rho^2} + \frac{N \partial N}{\rho \partial \rho} - \frac{1}{2} \left( \frac{\partial N}{\partial \rho} \right)^2 = -C_1 N^{3/2} + C_2 N^{5/2}.
\]

(E9)

Here,

\[
C_1 = 4 k_{30}^2 \beta_0^2 \frac{\pi f_0}{n} > 0, \\
C_2 = \frac{1}{2} \frac{q^2 \hat{n}}{m \epsilon_0} \frac{C_1}{\gamma_b^3 \beta_0^2 c^2 k_{30}^2} > 0.
\]

(E10)

The freedom of scale choice in \( r_s \) allows us to take \( C_1 = 1 \). Then we identify

\[
C_2 = \frac{\hat{\omega}_p^2}{2 \gamma_b^3 \beta_0^2 c^2 k_{30}^2} \equiv s_b,
\]

(E11)

where \( \hat{\omega}_p = \sqrt{q^2 \hat{n} / (m \epsilon_0)} \) is the on-axis plasma frequency, and \( s_b \) is the dimensionless self-field parameter defined in Eq. (48).

With this rescaling, the normalized density \( N \) within the beam is given by

\[
N \frac{\partial^2 N}{\partial \rho^2} + \frac{N \partial N}{\rho \partial \rho} - \frac{1}{2} \left( \frac{\partial N}{\partial \rho} \right)^2 = -N^{3/2} + s_b N^{5/2},
\]

(E12)

subject to

\[
N(\rho = 0) = 1, \\
\left. \frac{\partial N}{\partial \rho} \right|_{\rho = 0} = 0.
\]

(E13)

Equation (E12) can be simply integrated outward from the “initial” conditions at \( \rho = 0 \) in Eq. (E13) until the beam edge is reached at \( \rho = \rho_e \), where

\[
N(\rho = \rho_e) = 0.
\]

(E14)

It also follows directly from Eq. (E12) that

\[
\left. \frac{\partial N}{\partial \rho} \right|_{\rho = \rho_e} = 0.
\]

(E15)

Note that in this formulation only one dimensionless parameter \( s_b > 0 \) is necessary to specify the normalized density \( N \) of the parabolic equilibrium distribution.
As a practical matter, the numerical integration for \( N \) needs to be started from a small value of \( \rho \neq 0 \). A power series analysis of Eq. (E12) shows that the first few terms of the solution for small \( \rho \) are given by

\[
N = 1 - \frac{1 - s_b}{4} \rho^2 + \frac{(1 - s_b)(1 - 2s_b)}{64} \rho^4 + \frac{s_b(1 - s_b)(11 - 13s_b)}{4608} \rho^6 + \cdots. \tag{E16}
\]

For consistency with \( \partial N / \partial \rho < 0 \) for small \( \rho \), this expansion shows that the physical range of the self-field parameter \( s_b \) for the parabolic equilibrium is \( s_b \in [0, 1] \). The limit \( s_b = 0 \) corresponds to zero space-charge intensity with a shaped density profile reaching into the core of the beam (the analysis below shows that the density expansion truncates at the first two terms), and \( s_b \to 1 \) corresponds to the maximum space-charge limit with a flat density profile in the core of the beam.

Numerical solutions of Eqs. (E12) and (E13) for \( N \) versus \( \rho \) are plotted in Fig. 13 for values of \( s_b \in [0, 1] \). Due to an extreme sensitivity of the solution in \( s_b \) near \( s_b = 1 \), we employ an alternative parameter,

\[
p = -\ln(1 - s_b) \tag{E17}
\]

to characterize the solutions. The solutions are plotted out to the beam edge \( \rho = \rho_e \) where \( N = 0 \). In generating these solutions, it is convenient to integrate through \( N = 0 \) to allow calculation of \( \rho_e \) by numerical root finding. This can be accomplished by replacing \( N^{1/2} \to |N|^{1/2} \) and \( N^{3/2} \to |N|^{3/2} \) on the right hand side of Eq. (E12) without influencing the needed core solution of \( N(\rho) \) for \( \rho < \rho_e \). The extended solution for \( N \) with \( \rho > \rho_e \) has \( N \geq 0 \) and generally oscillates in \( \rho \) between zero and a value at some fraction of the core. Because \( \rho_e \) occurs where \( \partial N / \partial \rho = 0 \), \( \rho_e \) can be calculated by bracketed numerical root finding for \( \partial N(\rho) / \partial \rho = 0 \) near the first radial location where \( N \approx 0 \).

![Graph](image)

**FIG. 13:** For a parabolic equilibrium, the scaled density \( N = n/\hat{n} \) is plotted versus the scaled radial coordinate \( \rho = r/r_s \) numerically calculated from Eqs. (E12) and (E13) for \( p = 0, 2, \cdots, 10 \).

Note from the solutions in Fig. 13 that the core beam density profile becomes flat as \( s_b \to 1 \) (i.e., \( p \to \infty \)) out till \( \rho \) increases towards \( \rho_e \) where \( N \) drops to zero with a radial profile characteristic of the parabolic equilibrium choice of \( f_\perp(\psi_\perp) \). This edge shape extends deeper into the core of the beam as \( s_b \) (or \( p \)) decreases. In the limit \( s_b = p = 0 \), the exact solution to Eqs. (E12) satisfying Eq. (E13) is

\[
N = \left(1 - \frac{\rho^2}{8}\right)^2, \tag{E18}
\]

with a corresponding beam edge (i.e., where \( N = 0 \)) at \( \rho = \rho_e = 2\sqrt{2} \approx 2.8284 \). This result, consistent with the \( s_b = 0 \) numerical solution in Fig. 13, can be shown directly from the nonlinear equation (E12). However, the solution (E18) is most readily derived by solving the linear equation (E4) for \( \psi \) with \( K = 0 \) and employing Eqs. (E3) and (E8). Note that Eq. (E18) is consistent with the first two terms of the expansion in Eq. (E16) with \( s_b = 0 \), showing that the series expansion truncates in this limit.

The \( x \)-plane kinetic temperature \( T_x = \langle x^2 \rangle_{x_\perp} \) of the parabolic equilibrium can be calculated from Eq. (38) and previous results. This gives

\[
T_x(r) = \begin{cases} \frac{1}{2} [H_b - \psi(r)], & \psi < H_b, \\ 0, & \psi > H_b. \end{cases} \tag{E19}
\]
Equation (E7) can be applied to express this result in terms of the beam density \( n \) (in normalized and unnormalized form) as

\[
T_x = \frac{1}{3} \sqrt{\frac{n}{\pi f_0}} = \frac{1}{3} \sqrt{\frac{\hat{n}}{\pi f_0}} \sqrt{N}.
\]  

(E20)

This result, illustrating that \( T_x \propto \sqrt{n} \), is a consequence of the parabolic equilibrium choice for \( f_{\perp}(H_{\perp}) \). Equation (E20) can then be applied in Eq. (43) to explicitly calculate the parabolic distribution rms-edge emittance \( \varepsilon_b = 4\sqrt{\langle x^2 \rangle_{\perp} \langle x'^2 \rangle_{\perp}} \) in terms of the density (in normalized and unnormalized form) as

\[
\varepsilon_b^2 = \frac{2}{3} \frac{r_b^2}{\sqrt{\pi f_0}} \int_0^\infty dr \frac{rn^{3/2}}{\int_0^\infty dr \rho N^{3/2}} = \frac{2}{3} \sqrt{\frac{\hat{n}}{\pi f_0}} \frac{\int_0^{\rho_e} d\rho \rho N^{3/2}}{\int_0^{\rho_e} d\rho \rho N}.
\]  

(E21)

Alternatively, the emittance \( \varepsilon_b \) can be calculated from other equilibrium parameters using the matched envelope equation (39).

It is useful to employ \( H_{\perp} = \frac{1}{2} x_{\perp}^2 + \psi \) [see Eq. (35)] and Eq. (E7) to express the parabolic equilibrium distribution (E1) in the form

\[
f_{\perp}(x_{\perp},x'_{\perp}) = f_0 \left( -\frac{1}{2} x_{\perp}^2 + \sqrt{\frac{n}{\pi f_0}} \right) \Theta \left( -\frac{1}{2} x_{\perp}^2 + \sqrt{\frac{n}{\pi f_0}} \right) .
\]  

(E22)

Note that \( H_b \) has been eliminated in Eq. (E22). The maximum of the parabolic distribution occurs at \( f_{\perp}(x_{\perp} = 0, x'_{\perp} = 0) \), where

\[
f_{\perp}(x_{\perp} = 0, x'_{\perp} = 0) \equiv \hat{f} = \sqrt{\frac{f_0 \hat{n}}{\pi}}.
\]  

(E23)

Analogous to the waterbag equilibrium case discussed in Appendix D, parameters introduced in the formulation need to be related to usual parameters employed in accelerator physics. To do this, we first calculate the beam perveance \( Q \) in terms of the normalized density \( N(\rho) \) to be

\[
Q = \frac{q \lambda}{2 \pi \varepsilon_0 m c^2 \beta_0^2} = 2 s_b k_{30}^2 r_b^2 \int_0^{\rho_e} d\rho \rho N.
\]  

(E24)

Here, we have employed Eq. (E8) to scale the radial coordinate and density and Eq. (E11) to simplify the coefficient. Next, the definition of the statistical beam edge radius \( r_b = \sqrt{2 \langle x^2 \rangle_{\perp}} \) can be similarly applied to obtain

\[
\left( \frac{r_b}{r_s} \right)^2 = 2 \frac{\int_0^{\rho_e} d\rho \rho N}{\int_0^{\rho_e} d\rho \rho N}.
\]  

(E25)

Equations (E24) and (E25) then show that

\[
Q = \frac{k_{30}^2 r_b^2}{2 s_b (\int_0^{\rho_e} d\rho \rho N)^2}.
\]  

(E26)

The matched-beam envelope equation (39) shows that

\[
(k_{30}^2 \varepsilon_b)^2 = (k_{30} r_b)^4 - Q(k_{30} r_b)^2,
\]  

(E27)

and Eq. (E26) can be rearranged to give

\[
(k_{30} r_b)^2 = \frac{Q}{s_b} \left( \frac{\int_0^{\rho_e} d\rho \rho N}{(\int_0^{\rho_e} d\rho \rho N)^2} \right)^2.
\]  

(E28)

Equations (E27) and (E28) then show that

\[
\left( \frac{\varepsilon_b}{r_b} \right)^2 = Q \left( \frac{1}{s_b} \left( \frac{\int_0^{\rho_e} d\rho \rho N}{(\int_0^{\rho_e} d\rho \rho N)^2} \right)^2 - 1 \right),
\]  

(E29)
which can be employed with Eq. (E21) to identify \( \sqrt{\bar{n}/(\pi f_0)} \), a factor useful in setting the distribution scale [see Eq. (E23)], as

\[
\sqrt{\frac{\bar{n}}{\pi f_0}} = Q \left( 1 - \frac{\int_0^{\rho_e} d\rho \rho^3 N}{\left( \int_0^{\rho_e} d\rho \rho N \right)^2} - 1 \right) \frac{\int_0^{\rho_e} d\rho \rho N^{3/2}}{\int_0^{\rho_e} d\rho \rho N^{3/2}}.
\] (E30)

Note that the integrals in Eqs. (E24)–(E30) are pure functions of the dimensionless self-field parameter \( s_b \). Because \( Q/(k_{30}^2 r_b^2) \) is a dimensionless function of accelerator parameters, Eq. (E26) can be applied to numerically solve for \( s_b \), or alternatively \( p = -\ln(1 - s_b) \), in terms of accelerator parameters.

The rms-equivalent beam measure of relative space-charge strength \( \sigma/\sigma_0 = \sqrt{1 - Q/(k_{30}^2 r_b^2)} \) [see Eq. (47)] can be applied with Eq. (E26) to numerically calculate the parameters \( p \) and/or \( s_b = 1 - e^{-p} \) as a function of \( \sigma/\sigma_0 \). This result is shown in Fig. 14 over a broad range of relative space-charge strength. Note that small values of \( \sigma/\sigma_0 \) correspond to values of self-field parameter \( s_b \) extremely close of \( s_b = 1 \), demonstrating that \( s_b \) is inconvenient to describe parabolic equilibria with high space-charge intensity. As expected, \( p = 0 \) \((s_b = 0)\) corresponds to \( \sigma/\sigma_0 = 1 \) and a warm equilibrium with the applied-focusing force dominating, whereas \( p \to \infty \) \((s_b \to 1)\) corresponds to \( \sigma/\sigma_0 \to 0 \) and a cold, fully space-charge depressed equilibrium.

![FIG. 14: Parabolic equilibrium parameter \( p = -\ln(1 - s_b) \) versus rms-equivalent beam tune depression \( \sigma/\sigma_0 \) as calculated from Eq. (E26) and (47).](image)

To better understand properties of the parabolic equilibrium, we employ Eqs. (E25)–(E26) to plot the radial density and temperature profiles and the phase-space distribution in Figs. 15 and 16 for fixed applied-focusing strength \( (k_{30}^2 \equiv \text{const}) \) and fixed beam perveance \( (Q = \text{const}) \) as the relative space-charge strength \( (\sigma/\sigma_0) \) is varied. In Fig. 15(a) the scaled radial density profiles illustrate the sharpening of the parabolic equilibrium density profile with increasing relative space-charge strength (i.e., small \( \sigma/\sigma_0 \) or \( s_b \) close to unity) and bell-shaped for weak relative space-charge strength [i.e., \( \sigma/\sigma_0 \approx 1 \), or equivalently, small \( s_b \), with the density profile approximated by Eq. (E18)]. Similarly, the radial temperature profile in Fig. 15(b) indicate for strong relative space-charge forces that the temperature strongly decreases and flattens in the core of the beam before rapidly dropping to zero at the beam edge. Contours of the scaled distribution \( f_\perp(H_\perp)/\bar{f}_\perp \) are shown in Fig. 16(a)–(d) for values of \( \sigma/\sigma_0 \) corresponding to weak, intermediate, and strong relative space-charge strengths. The contours are generated by scaling Eq. (E22) to obtain

\[
\frac{f_\perp(H_\perp)}{\bar{f}_\perp} = \Theta \left( -\frac{x_\perp^2}{2\sqrt{\frac{\bar{n}}{\pi f_0}} + \sqrt{N}} \right) \Theta \left( -\frac{x_\perp^2}{2\sqrt{\frac{\bar{n}}{\pi f_0}} + \sqrt{N}} \right),
\] (E31)

and employing Eq. (E30) to calculate \( \sqrt{\bar{n}/(\pi f_0)} \). Specific contours with \( f_\perp/\bar{f}_\perp \equiv f \in [0, 1] \) are then generated by plotting

\[
|x_\perp| = 2\sqrt{\frac{\bar{n}}{\pi f_0}} (\sqrt{N - f})
\] (E32)

as a function of \( \rho = r/r_s = (k_{30} r)(r_0/r_s)/(k_{30} r_b) \) for \( \rho \in [0, \rho_f] \), where \( \rho_f \) is the numerical solution of \( N(\rho_f) = f^2 \). For large relative space-charge intensity \( (\sigma/\sigma_0 \ll 1) \), the flatness of the contours deep within the core of the distribution
indicates nearly force-free motion until the particle enters the nonlinear edge region. Various parameters for the equilibria presented in Figs. 15 and 16 are given in Table 16.

![Graph](image)

**FIG. 15:** Continuous-focusing parabolic equilibrium radial density and temperature profiles for fixed focusing-field strength \( k_{30}^2 = \text{const} \) and perveance \( Q = 10^{-4} \) with (rms-equivalent beam measure) relative space-charge strengths \( \sigma / \sigma_0 = 0.9, 0.8, \cdots, 0.1 \). In a) and b), the scaled density \( q^2/(2\epsilon \tan \gamma \beta \epsilon^2 c^2 k_{30}^2) n(r) \) and temperature \( T_s(r) \) profiles are plotted versus the dimensionless radial coordinate \( k_{30} r \). Values of \( \sigma / \sigma_0 \) correspond to the dimensionless equilibrium parameters in Table IV.

**TABLE IV:** Dimensionless parabolic equilibrium parameters in Figs. 15 and 19 calculated for specified \( \sigma / \sigma_0 \). The values of \( k_{30} \xi_b \) are evaluated for \( Q = 10^{-4} \), and all other quantities are independent of \( Q \).

To load the parabolic equilibrium distribution in either direct-Vlasov or PIC simulations, the general framework presented in Sec. III.B can be applied. For PIC loading of the parabolic distribution, the radial probability transform (51) for loading particle coordinates \( x_\perp \) can be expressed in scaled form as

\[
\frac{\int_0^\rho \hat{\rho} N(\rho \hat{\rho})}{\int_0^{\rho_c} \rho N(\rho) = \hat{u}_\rho}, \tag{E33}
\]

where \( \hat{u}_\rho \in [0, 1] \) is a uniformly distributed random variable. Equation (E33) is solved for \( \rho(\hat{u}_\rho) \in [0, \rho_e] \), and particle coordinates \( x_\perp \) are set using \( r = r_s \rho \) in Eq. (52). Values can be saved on a radial grid to efficiently load many particles.
FIG. 16: Parabolic equilibrium distribution contours \( f_{\perp}(H_{\perp})/\hat{f}_{\perp} \) are plotted as a function of \( k_{30r} \) and \( |x'_{\perp}| \) for the profiles shown in Fig. 15 with \( \sigma/\sigma_0 = 0.9, 0.5, 0.3 \), and 0.1 in (a)–(d). Contours are labeled with the value of \( f_{\perp}(H_{\perp})/\hat{f}_{\perp} \), and the edge contour \( (f_{\perp} = 0) \) is represented by the dashed curve.

with the same equilibrium parameters. To load the particle angles \( x'_{\perp} \) with the particle coordinates \( x_{\perp} \) already loaded, the probability transform (53) is applied with Eq. (E31). Carrying out the integrals leads to a quadratic equation that can be solved for the smallest physical solution as

\[
U(\hat{u}_{U}) = \sqrt{\frac{n}{\pi f_0}} \sqrt{N \left[ 1 - \sqrt{1 - \hat{u}_{U}} \right]}.
\] (E34)

Here, \( \hat{u}_{U} \in [0,1) \) is a uniformly distributed random variable, \( \sqrt{n/(\pi f_0)} \) is calculated (once) for the equilibrium parameters using Eq. (E30), and \( N = N(\rho) \) is the density at the loaded radial particle coordinate \( \rho = \sqrt{x^2_{\perp}}/r_s \). Particle angles are set using this value of \( U(\hat{u}_{U}) \) in Eq. (54). To efficiently carry out this angle loading procedure using Eq. (E34), \( N \) should be calculated once on a grid for \( \rho \in [0,\rho_e] \) and gridded values can then be interpolated for more accuracy.

**APPENDIX F: CONTINUOUS-FOCUSING THERMAL EQUILIBRIUM DISTRIBUTION**

The thermal equilibrium distribution has been studied extensively in nonneutral plasma physics[30, 101] and in accelerator physics by Reiser[31, 102] and others[32, 63, 64, 103, 104]. Here we review previous results in a format that allows easy contrast to other continuous-focusing distributions [see Secs. D and E] while presenting extensions needed for practical implementation of Vlasov simulation loads using standard inputs for accelerator physics. For a thermal equilibrium distribution in continuous-focusing, we take

\[
f_{\perp}(H_{\perp}) = \frac{m^2 c^2 \beta_b^2 \hat{n}}{2\pi T} \exp \left( -\frac{m^2 c^2 H_{\perp}}{T} \right)
\] (F1)
where \( \hat{n} = \text{const} \) is a constant density scale, and \( T = \text{const} \) is the thermodynamic temperature (expressed in energy units) in the laboratory frame. The thermal equilibrium distribution is a special class of stable Vlasov equilibria with \( \partial f / \partial H \leq 0 \) \([30]\). Within the weak coupling approximation \( (q^2 / \hat{n}^{-2/3} \ll T) \) any initial distribution function \( f_\perp(x_\perp, x'_\perp, s = s_i) \), however complex, relaxes through collisions to the thermal equilibrium form in Eq. (F1). This is true regardless of the details of the intervening evolution due to both collective and collisional processes. Even stable Vlasov equilibria must ultimately relax to thermal equilibrium form due to collisional effects outside the Vlasov model. Although the time scales for collisional relaxation are typically long relative to beam residence times in a machine, couplings to external error sources together with collective effects can result in enhanced rates of effective thermalization. In this regard, thermal equilibrium can be regarded as a preferred equilibrium state of the system.

The thermal equilibrium distribution is characterized by a radial kinetic temperature profile that is uniform. Direct calculation with Eqs. (14) and (F1) shows that

\[
T_x = T_y = \int \frac{d^2 x'_\perp x''_\perp f_\perp}{d^2 x'_\perp f_\perp} = \frac{T}{m\gamma_b\beta_b^2c^2} = T^* = \text{const.} \tag{F2}
\]

This constant temperature results in a diffuse beam edge since the spread in particle transverse energy will prevent an abrupt turning point of all particles. For the thermal equilibrium distribution it is convenient to define a dimensionless potential

\[
\tilde{\psi}(r) = \frac{\psi(r)}{T^*} = \frac{1}{T} \left[ \frac{m\gamma_b\beta_b^2c^2k_{30}^2}{2} + \frac{q\phi(r)}{\gamma_b^2} \right], \tag{F3}
\]

and make, without loss of generality, the choice of potential reference \( \phi(r = 0) = 0 \). Then Eqs. (36) and (F1) can be employed to calculate the equilibrium radial density profile in terms of \( \tilde{\psi} \). This gives

\[
n(r) = \int d^2 x'_{\perp} f_{\perp}(H_{\perp}) = \hat{n}e^{-\tilde{\psi}(r)}. \tag{F4}
\]

Because \( \tilde{\psi}(r = 0) = 0 \), \( \hat{n} \) is identified as the on-axis density of the equilibrium. Using Eq. (F4), the transformed Poisson equation (37) can be recast in scaled form as

\[
\frac{1}{\rho} \frac{\partial}{\partial \rho} \left( \rho \frac{\partial \tilde{\psi}}{\partial \rho} \right) = 1 + \Delta - e^{-\tilde{\psi}}, \tag{F5}
\]

and solved subject to the boundary conditions \( \tilde{\psi}(\rho = 0) = 0 \) and \( \tilde{\psi}_{\rho|\rho=0} = 0 \). Here, \( \rho \equiv r / (\gamma_b\lambda_D) \) is a scaled radial coordinate with \( \lambda_D \equiv [T/(m\bar{\omega}_p^2)]^{1/2} \) and \( \bar{\omega}_p \equiv [q^2\hat{n} / (\epsilon_0 m)]^{1/2} \) denoting the Debye length and plasma frequency formed from the (on-axis) density scale \( \hat{n} \), and \( \Delta \) is defined by

\[
\Delta \equiv \frac{2\gamma_b^3\beta_b^2c^2k_{30}^2}{\bar{\omega}_p^2} - 1. \tag{F6}
\]

Here, \( \Delta \in (0, \infty) \) is a positive, dimensionless parameter relating the ratio of applied to space-charge defocusing forces. Note that \( \Delta \) is simply a convenient rescaling of the usual self-field parameter \( s_b \equiv \bar{\omega}_p^2 / (2\gamma_b^3\beta_b^2c^2k_{30}^2) \) defined in Eq. (48) with

\[
\Delta = \frac{1}{s_b} - 1. \tag{F7}
\]

Strictly speaking, from the form of the thermal equilibrium density profile in Eq. (F4), it follows that the radial density profile \( n(r) \) is nonzero for any finite radius \( r < \infty \) and the thermal equilibrium distribution is only consistent with a free-space model with no conducting beam pipe \( (r_p \rightarrow \infty) \). However, since the density becomes exponentially small at large radii, this nonzero density inconsistency can be ignored if the cylindrical pipe radius \( r_p \) is chosen sufficiently large in comparison with the rms-envelope radius \( r_b \). Here we analyze properties of thermal equilibrium beams in the formally correct, infinite-system limit. Modified thermal-equilibrium-like distributions have also been presented that modify Eq. (F1) to introduce a sharp cutoff \([105]\). In some applications, this can improve the model at the expense of introducing another parameter to identify.
It is useful to employ \( H_\perp = \frac{1}{2} \mathbf{x}_\perp^2 + \psi \) [see Eq. (35)] and Eqs. (F3) and (F4) to express the thermal equilibrium distribution (F1) as
\[
 f_\perp(\mathbf{x}_\perp, \mathbf{x}_\perp') = \hat{n} e^{-\frac{x^2}{2}} e^{-\psi} = \hat{n}(r)e^{-\frac{x^2}{2}}. \tag{F8}
\]
The maximum of the thermal distribution occurs at \( \mathbf{x}_\perp = 0 \) and \( \mathbf{x}_\perp' = 0 \), where \( f_\perp (\mathbf{x}_\perp = 0, \mathbf{x}_\perp = 0) = \hat{n} \).

The thermal equilibrium distribution parameters corresponding to the on-axis density \( \hat{n} \), the thermodynamic temperature \( T \), and the parameter \( \Delta \) must be related to usual quantities associated with accelerator physics as discussed in Sec. III B.

To carry out this procedure, the transformed Poisson equation (F5) is first solved for \( \psi \) to obtain the thermal equilibrium density profile from Eq. (F4) and calculate the needed parametric constraints. This equation is highly nonlinear and must, in general, be solved numerically\[85, 106\], though closed form approximate analytical solutions have recently been constructed for both large and small values of \( \Delta \) that are highly accurate\[107\]. The numerical solution is illustrated in Fig. 17, where the normalized density \( n(r)/\hat{n} = \exp(-\psi) \) is plotted versus \( \rho = r/(\gamma_b \lambda_D) \) for values of \( \Delta \) covering several decades. Note that for small values of \( \Delta \), the scaled density \( n(r)/\hat{n} \) varies little from unity for \( \rho = 0 \) until intermediate-to-large values of \( \rho \) [corresponding to a large number of Debye lengths, since \( \rho = r/(\gamma_b \lambda_D) \)], where the density profile rapidly falls to exponentially small values as \( \rho \) increases by 4-5 units (i.e., Debye lengths). Note that the width in \( \rho \) of the radial falloff varies little with \( \Delta \), whereas the width of the flat, central region is a strong function of \( \Delta \). It will be shown that this highly nonlinear regime of small \( \Delta \), with \( \Delta \) smaller can correspond to beam parameters of practical interest when space charge strength is strong and the beam can be many Debye lengths in radial extent. In this regime, conventional numerical methods to integrate Eq. (F5) for \( \psi \) as a function of \( \rho \) from the on-axis values \( \psi(\rho = 0) = 0 \) and \( \partial \psi / \partial \rho |_{\rho=0} = 0 \) can fail. This parametric sensitivity is evident from the extreme flatness of \( n(\rho) \) for \( \rho \ll 1 \) and small \( \Delta \). Small, high-order derivative values of \( \psi \) at \( \rho = 0 \) sensitively determine the value of \( \rho \) where the rapid edge fall-off begins for \( \Delta \) small, complicating numerical solutions. We address this issue in Appendix G, where an analytical series solution of the scaled Poisson equation (F5) is developed that is valid within the core of the beam. Use of this series solution allows the integration to be initiated at a value of \( \rho > 0 \) where there is sufficient variation that standard numerical methods can be applied to generate solutions for \( \psi(\rho) \) for arbitrarily small values of \( \Delta \). In the emittance-dominated regime, \( \Delta \gg 1 \), and the solution to the scaled Poisson equation becomes \( \psi \simeq (1 + \Delta) \rho^2/4 \), and the scaled density profile \( n = \hat{n} \exp(-\psi) \) becomes Gaussian in \( \rho \) with
\[
 n(r) \simeq \hat{n} \exp\left[ -\frac{(1 + \Delta)}{4 \gamma_b^2 \lambda_D^2} \right]. \tag{F9}
\]

Note from Fig. 17 that \( n(r) \) is well approximated by Eq. (F9) even when \( \Delta \sim 1 \), showing that even modest values of \( \Delta \) correspond to weak space-charge.

![FIG. 17: For a thermal equilibrium, the scaled density \( n(\rho)/\hat{n} = \exp(-\psi) \) is plotted versus the scaled radial coordinate \( \rho = r/(\gamma_b \lambda_D) \) calculated from the solution of the scaled thermal equilibrium Poisson equation (F5) for \( \Delta = 10^{-\ell} \) with \( \ell = 0, 2, 4, 6, \) and, 8.](image-url)

Specification of the line-charge density \( \lambda \) [see Eq. (10)] and the transverse energy of the beam macrostate fixes the values of the constants \( \hat{n} \) and \( T \). Alternatively, we derive constraints to relate the thermal equilibrium parameters \( \hat{n} \), \( T \), and \( \Delta \), or equivalently, the effective Debye length \( \gamma_b \lambda_D = \gamma_b \sqrt{e_0 T/(q^2 \hat{n})} \), the scaled temperature \( T^* = T/(m \gamma_b^2 \beta_b^2 c^2) \), and \( \Delta \), in terms of the focusing strength \( k_{\beta_0} \), the perveance \( Q \) [see Eq. (22)], and the emittance \( \varepsilon_b \) [see Eq. (42)] using the formulation developed in Sec. III B. First, the beam line-charge density \( \lambda = 2 \pi q \int_0^\infty dr \, n(r) \) and the beam
rms-edge radius \( r_b = \sqrt{2 \langle r^2 \rangle_{\perp}} \) are expressed in terms of the thermal equilibrium density in Eq. (F4) as

\[
\lambda = \frac{\gamma_b^2 T}{2 q} \int_0^\infty dp \rho e^{-\tilde{\psi}},
\]

\[
r_b^2 = 2 \gamma_b^2 \lambda_D^2 \int_0^\infty dp \rho^3 e^{-\tilde{\psi}}.
\]  

(F10)

Note that the integrals occurring in Eq. (F10) depend only on the parameter \( \Delta \) with the solution \( \tilde{\psi}(\rho) \) formally given by the scaled Poisson equation (F5). Next, the rms-edge emittance \( \varepsilon_b \) is simply calculated directly from \( \varepsilon_b^2 = 2 r_b^2 \langle x'_{\perp}^2 \rangle_{\perp} \) and the thermal equilibrium distribution function (F1) to show that

\[
\varepsilon_b^2 = 4 T^* r_b^2.
\]  

(F11)

The matched-beam envelope equation (39) and \( \varepsilon_b^2 \) in Eq. (F11) can be used to express equivalently the rms-envelope radius \( r_b \) as

\[
r_b^2 = \frac{1}{k_{\beta 0}^2} (4 T^* + Q).
\]  

(F12)

Equation (F10) and the definition of the perveance \( Q = 2 q \lambda / (2 \pi e_0 m \gamma_b^3 \beta_b^2 c^2) \) obtains the constraint

\[
Q = T^* \int_0^\infty dp \rho e^{-\tilde{\psi}}
\]  

(F13)

and Eq. (F10) and (F11) can be combined to yield the constraint

\[
k_{\beta 0}^2 \varepsilon_b^2 = 4 T^* (4 T^* + Q).
\]  

(F14)

Then Eq. (F6) and the Debye length definition \( \lambda_D = (T/\hat{\omega}_p)^{1/2} \) yield

\[
k_{\beta 0}^2 = \frac{T^* (1 + \Delta)}{2 \gamma_b^2 \lambda_D^2}.
\]  

(F15)

Equation (F14) can be solved analytically for \( T^* \), and the constraints in Eqs. (F13)–(F15) expressed as

\[
T^* = \frac{Q}{8} \left( \frac{\sqrt{1 + 4 k_{\beta 0}^2 \varepsilon_b^2 / Q^2} - 1}{\sqrt{1 + 4 k_{\beta 0}^2 \varepsilon_b^2 / Q^2} - 1} \right)^{1/2} \int_0^\infty dp \rho e^{-\tilde{\psi}}
\]

(F16)

\[
(k_{\beta 0} \gamma_b \lambda_D)^2 = \frac{Q}{16} (1 + \Delta) \left( \sqrt{1 + 4 k_{\beta 0}^2 \varepsilon_b^2 / Q^2} - 1 \right).
\]

The constraint equations (F16) provide relations fixing \( \gamma_b \lambda_D, T^* = T/(m \gamma_b \beta_b^2 c^2) \), and \( \Delta \) in terms of \( Q, \varepsilon_b, \) and \( k_{\beta 0} \). Note that the integral \( \int_0^\infty dp \rho \exp(-\tilde{\psi}) \) is an implicit function of \( \Delta \) and must, in general, be calculated numerically to fully solve the constraints. In some applications it is useful to explicitly identify the on-axis density scale \( n(r = 0) = \hat{n} \) in terms of accelerator parameters. This can be done by rewriting Eq. (F15) as

\[
\hat{n} = \frac{2 e_0 m \gamma_b^3 \beta_b^2 c^2 k_{\beta 0}^2}{(1 + \Delta) q^2}.
\]  

(F17)

We first employ Eqs. (F10) and (F16) to reinforce the interpretation that the \( \Delta \) can be regarded as a parameter related to the relative space-charge strength. Using these constraints, the rms-equivalent beam tune depression \( \sigma / \sigma_0 \equiv \sqrt{1 - Q/(k_{\beta 0}^2 r_b^2)} \) [see Eq. (47)] and \( \Delta \) can be related by

\[
\frac{\sigma}{\sigma_0} = \left\{ 1 - \frac{\int_0^\infty dp \rho e^{-\tilde{\psi}}}{(1 + \Delta) \int_0^\infty dp \rho^3 e^{-\tilde{\psi}}} \right\}^{1/2}.
\]  

(F18)
This equation is solved numerically to plot $\Delta$ as a function of $\sigma/\sigma_0$ in Fig. 18. Note that strong tune depressions with $\sigma/\sigma_0 < 0.2$ correspond to extremely small values of $\Delta$. Because $\Delta$ is a single-valued function of $\sigma/\sigma_0$, the relative space-charge strength uniquely determines $\Delta$. Alternatively, the on-axis self-field parameter $s_b \equiv \omega_p^2/(2\gamma_0^3\beta_0^2 e^2k_{b0}^2) = 1/(1 + \Delta)$ [see Eq. (F7)] can be employed in place of $\sigma/\sigma_0$ to specify the scaled equilibrium. The physical range of $\Delta > 0$ implies that $s_b \in [0, 1)$ for the thermal equilibrium distribution. Note that $s_b$ will be extremely close to unity for small $\sigma/\sigma_0$ corresponding to beams with high space-charge intensity intensity, rendering $s_b$ a less convenient parameter to describe thermal equilibria in the space-charge-dominated regime. Generally, when numerically solving for needed values of $\Delta$ for thermal equilibria with high space-charge intensity ($\sigma/\sigma_0$ small), it can be more convenient to use $\Delta = e^p$ and solve for $p$ due to the sensitivity of the equilibrium specification in $\Delta$ [or $s_b = 1/(1 + \Delta)$].

![Graph](image)

FIG. 18: Thermal equilibrium parameter $\Delta$ plotted versus rms-equivalent beam tune depression $\sigma/\sigma_0$ as calculated from Eq. (F18).

To better understand properties of the thermal equilibrium, we employ Eqs. (F16) and (F17) to plot the radial density profile and the phase-space distribution in Fig. 19 for fixed applied-focus strength ($k_{b0}^2 = \text{const}$) and fixed beam perveance ($Q = \text{const}$) as the relative space-charge strength ($\sigma/\sigma_0$) is varied. In Fig. 19(a) the scaled radial density is plotted. For thermal equilibrium, the temperature profile is spatially uniform with $T_x = T_y = T/(m\gamma_b\beta_0^2e^2) = T^* = \text{const}$ [see Eq. (F2)]. Contours of the scaled distribution $f_{\perp}(H_{\perp})/f_{\perp}(0)$ are shown in Fig. 19(b)–(d) for values of $\sigma/\sigma_0$ corresponding to weak, intermediate, and strong relative space-charge strengths. Various parameters for the equilibria presented in Fig. 19 are given in Table V. Figure 19(a) illustrates how the thermal equilibrium density profile sharpens and becomes more step-function-like with increasing relative space-charge strength (i.e., small $\sigma/\sigma_0$, or equivalently small $T^*$) and Gaussian-like for weak relative space-charge strength [i.e., $\sigma/\sigma_0 \sim 1$, or equivalently large $T^*$, with the density profile approximated by Eq. (F9)]. Note that the peak density $n_0$ of the beam increases with increasing space-charge strength, whereas the rms-envelope radius $r_b = \sqrt{2\langle r^2 \rangle}$ decreases with increasing space-charge strength.

To load the thermal equilibrium distribution in either direct-Vlasov or PIC simulations, the general framework presented in Sec. III B can be applied. For PIC loading, the radial probability transform (51) for loading particle
result can be shown to be equivalent to distribution. Independent of particle position, we have using the constraint equation (F11) and this result shows that the angle loading given by Eq. (54) can be expressed as

\[ f_{\perp}(H_{\perp})/f_{\perp}(0) \text{ Contours, } \sigma/\sigma_0 = 0.5 \]

\[ f_{\perp}(H_{\perp})/f_{\perp}(0) \text{ Contours, } \sigma/\sigma_0 = 0.1 \]

coordinates \( \mathbf{x}_\perp \) is straightforward to apply using the normalized coordinates defined by

\[ \frac{\int_0^{\rho_0} d\rho \, \rho \, e^{-\psi(\rho)}}{\int_0^\infty d\rho \, e^{-\psi(\rho)}} = \hat{u}_\rho, \]

where \( \hat{u}_\rho \in [0, 1) \) is a uniformly-distributed random variable. Equation (F19) is solved for \( \rho(\hat{u}_\rho) \) and particle coordinates \( \mathbf{x}_\perp \) are set using \( r = \gamma_0 \lambda_\rho \rho(\hat{u}_\rho) \) in Eq. (52). Values can be saved on a radial grid in \( r \) out to a maximum cutoff value, where the beam density is negligible, to efficiently load many particles with the same equilibrium parameters. For loading the particle angles \( \mathbf{x}_\perp' \), the probability transform (53) can be greatly simplified for the thermal equilibrium distribution. Independent of particle position, we have

\[ U(\hat{u}_\perp) = -T^* \ln(1 - \hat{u}_\perp). \]

Using the constraint equation (F11) and this result shows that the angle loading given by Eq. (54) can be expressed as

\[ x' = \frac{\varepsilon \beta_t}{2r_b} \sqrt{-2 \ln(1 - \hat{u}_\perp) \cos(2\pi \hat{u}_\varphi)}, \quad y' = \frac{\varepsilon \beta_t}{2r_b} \sqrt{-2 \ln(1 - \hat{u}_\perp) \sin(2\pi \hat{u}_\varphi)}, \]

where \( \hat{u}_\varphi \in [0, 1) \) is a uniformly-distributed random number. Using two-dimensional probability transforms[89], this result can be shown to be equivalent to

\[ x' = \frac{\varepsilon \beta_t}{2r_b} \hat{g}_x, \quad y' = \frac{\varepsilon \beta_t}{2r_b} \hat{g}_y, \]

where \( \hat{g}_x \) and \( \hat{g}_y \) are independent, Gaussian-distributed random numbers with unit variance.
APPENDIX G: SERIES SOLUTION OF POISSON’S EQUATION FOR THE CONTINUOUS-FOCUSING THERMAL DISTRIBUTION

The scaled thermal equilibrium Poisson equation (F5), \((1/\rho)\left(\partial / \partial \rho\right)(\rho \partial \tilde{\psi} / \partial \rho) = 1 + \Delta - \exp(-\tilde{\psi})\) is most naturally numerically integrated for \(\tilde{\psi}\) as a function of \(\rho\) from the on-axis values \(\tilde{\psi}(\rho = 0) = 0\) and \(\partial \tilde{\psi} / \partial \rho\big|_{\rho=0} = 0\). In regimes of practical interest corresponding to very cold beams \((T\) small\), the parameter \(\Delta\) can be \(\sim 10^{-6}\) and smaller. For such small values of \(\Delta\), the scaled density profile \(n(\rho)/\hat{n} = \exp(-\tilde{\psi})\) (see Fig. 17) is very flat for small \(\rho\), and falls abruptly to zero at intermediate-to-large values of \(\rho\). This highly sensitive parametric dependence on \(\Delta\) renders the direct numerical integration difficult (i.e., the system is very stiff) using conventional numerical methods. For this reason, most work on thermal equilibrium beams has focused on values of \(\Delta\) sufficiently high that numerical problems are easily avoided. Here, we outline a series solution for the thermal equilibrium density profile\(^{[106]}\) valid for intermediate values of \(\rho\) that can be employed to construct accurate numerical solutions over the entire range of \(\rho\) for arbitrarily small values of \(\Delta\), thereby enabling the analysis of arbitrarily-low-temperature thermal equilibrium beams. The methods described are employed to generate the solutions needed for the explicit calculation of thermal equilibrium quantities illustrated in Appendix F.

Operating on the scaled Poisson equation (F5) with \(\int_0^\rho d\tilde{\rho} \tilde{\rho}\), we obtain
\[
\rho \frac{\partial \tilde{\psi}}{\partial \rho} = \frac{1 + \Delta}{2} \rho^2 - \int_0^\rho d\tilde{\rho} \tilde{\rho} e^{-\tilde{\psi}(\tilde{\rho})}.
\]
This equation can be interpreted as the radial force balance equation for a thermal equilibrium beam\(^{[106]}\). Introducing the scaled radial coordinate \(R\) and density \(N\) defined by
\[
R = \frac{1 + \Delta}{4} \rho^2 = \frac{1 + \Delta}{4} \left(\frac{r}{\gamma_0 \lambda_D}\right)^2,
\]
\[
N = \frac{e^{-\tilde{\psi}}}{1 + \Delta} = \frac{n(r)}{\hat{n}(1 + \Delta)},
\]
this radial force-balance equation can be expressed in an equivalent form, with no free-parameters, as
\[
R \frac{\partial}{\partial R} N(R) = -R N(R) + N(R) \int_0^R d\bar{\rho} N(\bar{\rho}).
\]
(G2)
The solution to Eq. (G2) can be expressed as a power series of the form
\[
N(R) = \sum_{i=0}^\infty \alpha_i R^i,
\]
subject to \(N(R = 0) = (1 + \Delta)^{-1}\). Substituting Eq. (G3) into Eq. (G2) and equating like powers of \(R\) gives the recursion relations
\[
\alpha_0 = (1 + \Delta)^{-1},
\]
\[
\alpha_1 = -(\alpha_0 - \alpha_0^2),
\]
\[
\alpha_2 = -\frac{1}{2} \alpha_1 + \frac{3}{4} \left(\frac{1}{2} \alpha_0 \alpha_1 + \frac{1}{2} \alpha_1 \alpha_0\right) = \frac{1}{2} (\alpha_0 - \alpha_0^2) - \frac{3}{4} \alpha_0 (\alpha_0 - \alpha_0^2),
\]
\[
\vdots
\]
\[
\alpha_{i+1} = -\frac{\alpha_i}{i+1} + \frac{i+2}{2(i+1)} \sum_{j=0}^i \frac{\alpha_j \alpha_{i-j}}{j+1(i-j+1)}.
\]
(G4)
Note that all \(\alpha_i\) with \(i \geq 1\) can be calculated in terms of \(\alpha_0 = (1 + \Delta)^{-1}\), and thus the coefficients \(\alpha_i\) can be regarded as known functions of \(\Delta\). From Eqs. (G1) and (G3) the thermal equilibrium density profile \(n(r)\) can be expressed as
\[
n(r) = \hat{n} + \hat{n}(1 + \Delta) \sum_{i=1}^\infty \alpha_i \left[\frac{1 + \Delta}{4} \left(\frac{r}{\gamma_0 \lambda_D}\right)^2\right]^i,
\]
(G5)
and the solution for $\psi(\rho) = -\ln[n(\rho)/\tilde{n}]$ is given by

$$\tilde{\psi}(r) = -\ln \left\{ 1 + (1 + \Delta) \sum_{i=1}^{\infty} \alpha_i \left[ \frac{1 + \Delta}{4} \left( \frac{r}{\gamma_0 \lambda_D} \right)^2 \right]^i \right\}. \quad (G6)$$

Note from Eq. (G5) that $[\partial n/\partial r]_{r=0} = 0$ and $[\partial^2 n/\partial r^2]_{r=0} = -\Delta \tilde{n}/(2\gamma_0^2 \lambda_D^2)$, corresponding to weak downward concavity in the density profile for $\Delta \ll 1$.

Detailed analyses\cite{ref107} show that for $\Delta \ll 1$, the power-series solutions for $n(r)$ and $\psi(\rho)$ given by Eqs. (G5) and (G6) rapidly converge for large values of $\Delta$ (weak space-charge, see Sec. F) for all $\rho \in [0, \infty)$. For small $\Delta \ll 1$ (strong space-charge), the solutions are found to rapidly converge for $\rho$ ranging from the beam center ($\rho = 0 = r$) to near the outer radial edge of the beam [$\rho \sim \ln(\pi/\Delta)$] where the density profile begins falling rapidly. The expansions fail in the region of rapid density variation at the beam edge. When constructing solutions to the thermal equilibrium Poisson equation (F5), the power-series solutions can be employed out to some sufficiently large value of the radial coordinates $\rho = \rho_c$, where the series solution is still reliable, but the local variation in the density profile in $\rho$ is large enough to allow reliable initialization of numerical integration for $\rho \geq \rho_c$ with standard methods. Applying the series in small radial steps in $\rho$ out to $\rho = \rho_c$, where $N(\rho_c) \approx 0.98$ appears to be an adequate, simple to implement criterion. Rather then numerically integrating the scaled Poisson equation (F5) from $\rho = \rho_c$, it is convenient to recast the equation in terms of $N = \exp(-\tilde{\psi})$ instead of $\tilde{\psi}$ and integrate

$$\frac{\partial^2 N}{\partial \rho^2} + \frac{1}{N} \left( \frac{\partial N}{\partial \rho} \right)^2 - \frac{1}{\rho} \frac{\partial N}{\partial \rho} = N^2 - (1 + \Delta)N \quad (G7)$$

from the “initial” conditions $N(\rho_c) = \tilde{n}$ and $\partial N/\partial \rho |_{\rho=\rho_c}$ calculated from Eq. (G5). In integrating this equation, $(\partial N/\partial \rho)^2$ vanishes much faster than $1/N$ diverges in the low-density tail, so $1/N$ can be replaced by $1/(N + \epsilon)$ with $\epsilon$ sufficiently small to avoid problems with numerical evaluation of the equations.

Procedures given above can be applied to calculate highly accurate solutions for $N$ or $\psi = -\ln N$ for arbitrary values of $\Delta$ – however large or small. This method was applied to verify a closed-form, approximate analytical solution for $N$

$$N \approx \frac{(1 + \frac{1}{2} \Delta + \frac{1}{24} \Delta^2)^2}{(1 + \frac{1}{2} \Delta I_0(\rho) + \frac{1}{24} [\Delta I_0(\rho)]^2)^2} \quad (G8)$$

that is derived in Ref. \cite{ref107} and found to be highly accurate for $\Delta < 10^{-2}$ outside of the extreme tail where $N$ is exponentially small. Here, $I_0(x)$ denotes an order 0 modified Bessel function\cite{ref99}.
