Abstract:

A summary of the target fragment mass distributions from the interaction of 8.5 - 14,500 MeV/nucleon lighter heavy ions (C - Ne) with targets ranging from Cu to U is presented. The measured distributions are compared with predictions of the intranuclear cascade model as well as semi-empirical prescriptions to describe fragment yields.
1. Introduction

For over ten years, nuclear chemists have measured the target fragment isobaric yield distributions from relativistic \( E_{\text{proj}} \approx 250 \text{ MeV/nucleon} \) nucleus-nucleus collisions. For over five years, similar measurements have been made for intermediate \( E_{\text{proj}} \approx 100 \text{ MeV/nucleon} \) energy nuclear collisions. In this paper, we summarize the results of these measurements and compare them to relevant semi-classical models of nucleus-nucleus collisions. In doing so, we hope that the data will serve as guides to more sophisticated measurements of these reactions and as suitable benchmarks for calculations of the various reaction mechanism(s) involved. The data may also be of interest to those who study cosmic ray interactions with matter.

2. Results

A representative sample of the data on target fragment isobaric yield distributions for the interaction of lighter heavy ions \((C - Ne)\) with \(Cu, Ho, Au\) and U is shown in Figures 1-7. Wherever possible we have shown the individual fragment isobaric yields (which are uncertain to \(\pm 40\%\)). Where this was not feasible, a smooth curve was fitted to the measured yields. Additional data for the fragmentation of Ag\(^{15,16}\), Sm\(^{9,17}\) and Ta\(^{6,18}\) exist. Qualitatively, one observes the fragmentation of U to be dominated by fission de-excitation of most fragments produced in the initial nucleus-nucleus collision. Spallation-like processes contribute to the yields of fragments with \( A > 70 \) and multifragmentation results in products with \( A < 60 \). For Au target fragmentation one observes complete fusion processes at the lowest projectile energies resulting in evaporation residues and fission fragments. As the projectile energy is raised incomplete fusion processes become increasingly important until about 35 MeV/nucleon.
where complete fusion processes are negligible. Further increases in projectile energy result in increasing spallation and fragmentation processes with Au and with Ho, fission decreases as a fragment de-excitation mechanism as the projectile energy increases. In the case of a nucleus like Ho which only fissions when it is made to rotate rapidly, the decrease in fission cross section with increasing projectile energy can be linked directly to the decrease in the angular momentum of the fissioning system. From $35 \leq A \leq 55$, the fragment yields from Cu fragmentation decrease roughly exponentially with decreasing fragment mass. The slope of these mass yield curves is greatest for the lowest energies and is least for the highest projectile energies, presumably reflecting the increase in the yields of lower A fragments with increasing projectile (excitation) energy resulting in more particle evaporation.

3. Semi-empirical models

There have been a number of attempts to describe the fragment mass distributions from high energy nuclear collisions in terms of semi-empirical models. One of the potentially most powerful of these models is the universal scaling law of Campi, Desbois and Lipparrini. This scaling law states that if one defines $X = A_{\text{frag}}/A_{\text{tgt}}$, then for a given projectile and energy, the fragment isobaric yields from all target nuclei expressed as a function of $X$ fall on a common universal curve. Thus, in principle, one need only measure the isobaric distribution for a given projectile and energy for a single target nucleus and one will then know the distribution for all target nuclei. In Figure 8, we show the application of this idea to the fragment mass distributions from the interaction of $400 \text{ MeV/nucleon } ^{20}\text{Ne}$ with Cu, Ho, Ta and Au. One observes some validity of the scaling law for the (Ta,Au) and (Cu, Ho) pairs but no universal scaling due to the fundamentally different shapes of the isobaric yield distributions. The (Ta,
Au) pair exhibits a U-shaped distribution not evident in the fragmentation of Cu, Ho. Perhaps a judicious application of the scaling law to extrapolate amongst smaller ranges of target nuclei is possible.

Many years ago, Rudstom parameterized the systematics of spallation yields from energetic p-nucleus collisions in a five parameter formula. This semiempirical formula was extended to encompass the yields of all types of fragments from p-nucleus collisions by Silberberg and Tsao. We thought it would be interesting to compare the predictions of the Silberberg-Tsao formula for p-nucleus collisions and the data for nucleus-nucleus collisions involving projectiles of equivalent total energy. (Figure 9). The magnitude (but not the shape) of the Silberberg-Tsao cross sections has been adjusted to reflect the difference between the p-nucleus and nucleus-nucleus total reaction cross sections. The agreement between the predicted and measured values of the cross sections for the Cu target nucleus is good. This agreement substantiates the oft-made claim that p-Cu and heavy ion-Cu reactions are very similar. (There is a difference between predicted and measured near-target cross sections, perhaps reflecting the influence of differing peripheral processes in p-Cu and nucleus-Cu collisions.)

When one compares predicted and measured cross sections for the Ho target nucleus, the agreement is not so good. The measured yields of fragmentation products (A < 40) are substantially greater in the nucleus-Ho collisions compared to the p-Ho systematics and the shapes of the mass distributions at the lower energy are not very similar. It would appear that one needs a new semi-empirical parameterization to adequately describe fragment cross sections from nucleus-nucleus collisions.
4. **Semiclassical models**

One of the earliest models of high energy nuclear collisions was the intranuclear cascade model. In this model, nuclear collisions are simulated by following the individual nucleon-nucleon collisions (during a reaction) using relativistic classical mechanics. The initial positions and momenta of the colliding nucleons are chosen randomly according to a prescribed distribution. For example, the momentum distribution is often chosen to be that of a cold Fermi gas. Such models traditionally ignore Pauli blocking of the nucleon-nucleon collisions, nuclear binding, etc. The single particle phase space density \( f(r,p,t) \) of the nucleons obeys a Boltzmann equation with collision terms but no mean field term.

\[
\frac{\partial}{\partial t} f + \mathbf{v} \cdot \nabla f - \int \frac{d^3p_2 d^3p_1 d^3p_2'}{(2\pi)^6} 
\]

\[
x \cdot \mathbf{v}_{12} \sigma(p+p_2 \rightarrow p_1+p_2') (f f_1 f_2) \delta^3(p+p_2-p_1-p_2'),
\]

where \( \mathbf{v}_{12} \) is the relative velocity of the pair of particles colliding with cross section \( \sigma(p+p_2 \rightarrow p_1+p_2') \). The time evolution of \( f(r,p,t) \) is followed using Monte Carlo techniques.

Our favorite version of this model is that developed by Yariv and Fraenkel. Using this model, one can calculate the mass number, atomic number, excitation energy, recoil and angular momentum of the projectile and target fragments from a collision. The de-excitation of the target fragments formed in the primary interaction is calculated using yet another Monte Carlo method developed by us. In this calculation the decay of the primary fragments by evaporation and fission is followed.
In Figures 10 and 11, we compare calculations made using this semiclassical model with measured fragment mass distributions for Ho and U targets. For the case of the U target, the good agreement between the calculations and the data indicates that the de-excitation correctly describes the fission decay of the excited primary fragments. For the case of the Ho target, the agreement between the predicted and measured mass distributions is still acceptable although the measurements, particularly at the higher energy, show the occurrence of multifragmentation (yields of fragments with A<60), a phenomenon not included in the cascade model or the de-excitation calculation.

At intermediate projectile energies, many of the individual nucleon-nucleon collisions are Pauli-blocked. This can be taken into account by modifying equation (1) to include Pauli-blocking terms, i.e.,

$$\frac{\partial f}{\partial t} + v \cdot \frac{\partial f}{\partial r} = -\int \frac{d^3p_2 d^3\hat{p}_1 d^3\hat{p}_2}{(2\pi)^6}$$

$$\times v_{12}\sigma(p+p_2+p\hat{1}+p_2)[f_2(1-f\hat{1})(1-f_2)f\hat{1}f_2(1-f)(1-f_2)]$$

$$\times \delta^3(p_1+p_2-p\hat{1}-p_2)$$

The (1-f) terms simulate the effects of Pauli blocking by inhibiting scattering to regions of high phase space density. Some success has been obtained using this model to describe the fragment mass distributions in intermediate energy nuclear reactions but the lack of a mean field term in this equation does not allow a full description of all aspects of these reactions.
5. **Summary**

We have presented all the available data on target fragment mass distributions in intermediate and high energy nucleus-nucleus collisions. We have shown how these data may be understood in terms of semiclassical models for the reactions. We have pointed out shortcomings in various semi-empirical approaches to describing these reactions.

6. **Acknowledgements**

We wish to thank the many scientists who have collaborated with us in making the measurements described herein. This work was supported in part by the U.S. Dept. of Energy under contracts DE-AC03-76SF00098 and DE-AM06-76RL02227.
