A B S T R A C T
During the past two decades, Swedish government policy has decentralized post-secondary education throughout the country. We investigate the economic effects of this decentralization policy on the level of productivity and innovation and their spatial distribution in the national economy. We find important and significant effects of this investment policy upon economic output and the locus of knowledge production, suggesting that the decentralization has affected regional development through local innovation and increased creativity. Our evidence also suggests that aggregate productivity was increased by the deliberate policy of decentralization. Finally, we estimate the spillovers of university investment over space, finding that they are substantial, but that they are greatly attenuated. Agglomerative effects decline rapidly; roughly half of the productivity gains from these investments are manifest within 5–8 km of the community in which they are made.

1. Introduction

Sweden undertook a conscious spatial decentralization of its system of higher education beginning in 1987. This policy was motivated by a complex variety of political, social, and economic factors. In this paper, we analyze the effects of university research activity on economic productivity and upon the level and distribution of innovative activity in the economy. We provide quantitative evidence on the effects of the decentralization policy upon output per worker and upon the award of commercial patents for innovations and discoveries. We also provide new evidence that the policy has increased aggregate productivity and economic output, but that the economic impacts are greatly attenuated over space and distance.

From a broader perspective, there has been intense debate in developed countries about the role of university research, and the spin-offs of that research, in stimulating regional development. The popular press in Sweden has documented – endlessly it seems – the role of Stanford and Berkeley in fostering the growth of the Silicon Valley in Northern California. One implication seems to be that investment in post-secondary education affects the aggregate level of economic activity as well as its geographical distribution.

A related line of research has sought to understand more generally the economic role of space in affecting economic growth and increased productivity. Recent theories have stressed the role of knowledge spillovers in cities in generating growth, distinguishing between spillovers among firms within an industry (Marshall–Arrow–Romer externalities) and spillovers across industries arising from the colocation of economic activity in cities (Jacobs externalities). Work by Glaeser et al. (1992) is consistent with the importance of industrial diversity (rather than concentration) in fostering economic growth in the US. In contrast, Henderson et al. (1995) find that concentration facilitates growth in mature capital-intensive industries.

The precise linkages among educational investments, knowledge, spillovers and regional output remain unclear, and, in the words of Jaffe (1989), the “transport mechanism” is not well understood. The work of Romer (1986, 1990), Lucas (1988), and especially Fujita (1988) suggests that these external economies from concentration are endogenous outcomes caused by the colocation of firms and workers. In any case, it is now quite natural to recognize “productivity gains from the geographical concentration of human capital” (Rauch, 1993). This line of research is reviewed by Moretti (2004).

One specific mechanism linking educational investment to regional output is innovation itself. If educational investment stimulates local innovation and creativity, productivity gains may arise...
from the new knowledge whose production is facilitated by the pattern of spatial investment (Jaffe et al., 1993). We analyze this mechanism using the natural experiment of decentralization of higher education in Sweden. We trace the implications of this exogenous change in policy upon productivity and upon the level and distribution of innovative activity in the national economy. In conducting this analysis, we rely upon unique bodies of data – annual estimates of output per worker for each of 284 local civil divisions in Sweden and comprehensive records on patent awards, which include the home address of the inventor.

Our results document the surprisingly large effects of these specific university investments in stimulating creativity and regional productivity. We quantify the importance of university research in the production of patents, although we cannot distinguish between the direct activities of a university and its ancillary role in inducing the nearby location of research-intensive industry. Our results also document the effects of university investments on local economic activity, especially increases in output and worker productivity. To be sure, we cannot distinguish fully between the direct and the induced effects of university investment on patents and productivity. From the viewpoint of the localities receiving the investment, it matters little whether the local university produces graduates of higher productivity who will work in the region or whether more productive firms are induced to work in the region by the presence of the educational facility.

But this distinction is crucial from a societal viewpoint. In this instance, we can estimate the net effect of the spatial rearrangement of economic activity upon aggregate output. When our statistical results are used to compare the economic effects of increased university investment in the pre-existing institutions (in older, denser, urban regions) with equivalent investments in new institutions (in less dense, less urbanized regions), the results suggest that the decentralization policy has led to an increase in aggregate output and aggregate creativity. The estimated effects are not large, but they persist across specifications and statistical models. These results are consistent with recent work by Rosenthal and Strange (2003, 2005, 2008) which suggests that external economies of agglomeration are sharply attenuated with distance and that the marginal effects upon agglomeration of additional employees at small new establishments are larger than the economic effects of equivalent investments at traditional locations. Our results are also consistent with those reported by Arzaghi and Henderson (2006) for New York City – which suggest significant productivity gains from the collocation of firms in Manhattan, but gains which attenuate rapidly over space.

An earlier paper, Andersson et al. (2004), hints at some of these findings about university investment policy. That work, based on more primitive data and statistical methods, suggested a linkage between university investment and economic output. Previous work did not investigate patent activity as a transmission device or the attenuation of economic effects over space.

Section 2 provides a brief review of Swedish university policies and innovation during the last few decades. Section 3 surveys the literature on university research, knowledge spillovers, and innovation during the last few decades. Section 4 presents the data and the models used in our statistical analysis. Section 5 summarizes our results and conclusions.

2. Swedish university policy

As recently as 1977, only six universities operated in Sweden, a country of nine million people about the size of California. The locations of these institutions, the old established universities and five technical institutes,1 are depicted in Fig. 1. In addition, 14 small colleges existed; each was affiliated with a university. In 1977, the university structure was changed, establishing 11 new institutions, raising the status of the 14 colleges and placing all 36 universities, institutes and colleges (located in 26 different municipalities) under one administration. The “new” university structure is also indicated in Fig. 1.

In almost all cases, the sites chosen for the new institutions of higher education were formerly occupied by teacher training schools, engineering academies, or by military training facilities.2 In the review of this expansion of the university system prepared by the National Agency for Higher Education (“Högskoleverket”) in

---

1 Universities were located in Stockholm, Göteborg, Lund, Uppsala, Linköping, and Umeå. In addition, there were three large technical institutes in Stockholm (The Royal Institute of Technology; the Karolinska Institute of Medicine; and the Stockholm School of Economics), as well as two others (The Chalmers Institute of Technology in Göteborg and the Institute of Agriculture near Uppsala).

2 Five sites of university expansion formerly housed institutions of preschool education; eight formerly housed affiliates of Sweden’s Institute of Education; two had been schools of naval science (several sites had housed more than one of these facilities).
1998, only one instance is reported in which economic considerations affected the location chosen for a new institution. Of course, this review was prepared ex post by the government agency that supervised the expansion, and there may have been political or partisan reasons for this characterization. A review of the parliamentary acts establishing the new universities also gives short shrift to the role of local fiscal policy in the choice of locations for the new universities. But, for the parliament as well as for the government agencies, increased student access may simply be a rationale for the public investments. In recent interviews with participants in the expansion process, undertaken in response to reviewer comments, we found little evidence that local fiscal policy affected the choice of location for the institutions.

Of course, none of this really proves that the locations of the new institutions were not chosen primarily to employ idle resources, and alternative explanations should be borne in mind. However, it is worth noting that during the period 1968–1976 (before the policy was undertaken) municipalities in which the new institutions were located grew by 4.9% in population. Municipalities in which the old institutions were located declined by 4.3%. Population increased by 6.5% in the remaining cities in Sweden. During the period 1977–1999 (after the policy was introduced), the cities in which the new institutions were located grew by 4.6% in population; cities in which the old institutions were located grew by 1.4%. The remaining cities in Sweden increased by 7.1% in population.

3 The college established in Karlsskrona–Ronneby was in an area of high unemployment caused by the closing of a major shipyard. In all other cases, the new colleges were located to replace or upgrade existing post-secondary school and teacher-training activities. See De första 20 åren (1998), for an extensive discussion.

5 For example, in the enabling legislation for the initial expansion (Government Proposition 1976/77: 59), the explicit aim of increasing the opportunities for a socially and geographically diverse student body was stressed. ("En högskoleomhet i varje ort," roughly "a unit of higher education in every locality," was the slogan.) In subsequent legislation (e.g., Propositions in 1986/87 and 1987/88), there is no reference to local fiscal policy as a motive, but in more recent legislation (Proposition 1996/97), there is one reference to the unemployment rate in Malmo at the time that the higher education facility was authorized.

6 On the contrary, an interview with a senior official in the budget office at the time of the university expansion revealed that the Budget Minister himself intervened in the localization process to diminish the average distance of these new institutions from concentrations of potential students, referring specifically to the motive of increasing the employment rate. See De första 20 åren (1998), for an extensive discussion.

8 The university decentralization can be interpreted simply as Keynesian fiscal policy at the regional level. Two other potential effects of this policy can be identified. The first is an expectation that the enhanced institutions would provide spillovers or local externalities that could improve productivity and lead to regional expansion by existing companies or by start-up firms. Alternatively, research at a regional college or university could foster directly innovation and increased entrepreneurial activity – the "Silicon Valley model."

Of course, these latter effects are not mutually exclusive. Exogenous changes in the distribution of university resources may induce spillovers among firms, leading to increased productivity and economic output directly. Increased innovative activity represents one mechanism by which regional output and creativity could have been increased.

In Section 4, below, we investigate these connections, analyzing the changes in productivity induced by these investments and the subsequent changes in the spatial distribution of innovative activity and the level of creativity in the economy. It is surely true that there are lags between investments in research staff, facilities, and resulting levels of innovation. There are further lags between creative output, its embodiment in a patent granted after review, and its effects on productivity and economic output. Even beyond any lags in observing responses, the complementarity between the specialties chosen for education and research by the various regional colleges (science, technology, social science, etc.) and the economic activities in the region probably matters in generating innovative activity. We investigate these issues.
3. University research, production, and innovation

As Marshall and later Krugman (1991), Feldman (1994), Jaffe et al. (1993), Audretsch and Feldman (1996), and others have emphasized, space itself forms a barrier to the diffusion of knowledge. Daily face-to-face contact may be quite important in the diffusion of results from scientific research and development (R&D). It may thus be beneficial for commercial developers to locate close to universities and other centers of basic research. However, geographic proximity to other firms in the same industry may be of even greater importance in stimulating applied research and innovations which improve practice. Florax (1992), however, found that proximity to a college or university is not a significant factor in explaining regional variations in the incidence and location of new start-up companies.

During the last two decades, data on patents have been relied upon increasingly in investigating the production of knowledge (See Griliches, 1984). Using patent counts, Acs et al. (2002) found that both university research and private R&D exerted substantial effects on innovative activity and patents across US metropolitan areas, with a clear dominance of private R&D over university research.

Jaffe (1986) investigated the link between patents and the R&D activities of firms. His research suggests that knowledge transfers occur more easily among companies in regions with a high output of patents. Companies performing research in areas where a considerable amount of research is carried out by other companies also appear to generate more patents per dollar spent on R&D than companies located in areas where relatively little research is carried out by other companies. Thus, clusters of research companies facilitate the diffusion of new knowledge. Jaffe (1989) analyzed time series data on corporate patents for US states, corporate R&D, and university research, investigating spillovers from academic research. He found a significant effect of university research on corporate patents. His results also suggested that university research may have an indirect effect on local innovation by inducing R&D spending by private firms.

Varga (1998, 2000) related the output of R&D (measured by regional registrations of more than 4000 product innovations) to annual expenditures on university research as well as the number of employees in laboratories and research institutes within private companies. Using aggregate data for US states and metropolitan areas, he found important returns to scale and scope. Varga concluded that there is a critical mass relating the density and size of a region to the output of innovative activity. In this process, university inputs “matter.”

Fischer and Varga (2003) related patent applications in 99 political districts in Austria to aggregate research expenditures by private firms in those districts and to estimates of university research expenditures in those districts, finding significant effects of inputs on patent applications. The interpretation of the results of this investigation is somewhat problematic, but they are suggestive of a linkage.

4. Hypotheses and data

Our models estimate the effects of university-based researchers on the productivity and innovations of local areas, and they compare the effects for the older established (pre-1977) universities with those for the newer, smaller, and less centralized institutions established since then. Decentralization is measured by the spatial distribution of the post-graduate university research staffs, and productivity is measured by output per worker. Innovative activity is measured by the award of patents by the Swedish Patent and...
Registration Office, which predates the European Patent Office and which has more extensive coverage.

As reported in Fig. 2, the number of post-graduate researchers employed in Swedish universities tripled, from 6000 in 1985 to almost 20,000 in 2001. The 15% per year increase in the post-graduate research staff includes much larger percentage increases in those employed at the smaller and newer institutions. Currently about one-eighth of research staff positions are located at these new colleges, and the scale of these positions is expected to grow.13

During this same period, university enrollment increased by almost 90%, from 160,000 students to 306,000. There was an increase of roughly 63,000 students in the older established universities and 83,000 students in the newer universities. The capacity of the newer colleges and universities more than tripled to 114,000 students.

During the period beginning in 1985, annual increases in real output per worker averaged about 2.3% per year in Sweden, with productivity increases as large as 5.5% (in 1993) and as low as minus 2.5% (in 1990). Fig. 3A reports aggregate annual productivity increases during the 1985–1998 period. Annual increases in new knowledge (at least, as measured by commercial patents) also varied significantly. Between 1994 and 2001, about 16,000 commercial patents were approved. Annual approvals ranged from a low of about 1500 patents granted in 1995, to a high of almost 2500 patents granted in 2001. Fig. 3B reports the trends in patent awards per 10,000 workers.

The record for each patent award includes both the date of the award and the date of the application. It generally takes about 3 years for a successful application to be approved. In 1994, for example the average time interval from application to award was 2.5 years, and 80% of approvals were made within 4 years of the initial application. In 2001, the average time interval increased to 2.9 years, and three quarters of approvals were made within 4 years of application.

As noted above, output per worker is recorded annually for each of 284 municipalities.14 Patent data record the home address of the innovator(s). Because inventors may live in one municipality and work in another, we allocate each patent to the (geographically larger) labor market area in which the inventor lives.15 Fig. 4 provides a

---

13 It should be noted that the allocation of staff positions is made centrally by the Ministry of Education, not by the institutions themselves using “soft money.”

14 Gross regional product is estimated by the value-added approach for 45 different business sectors at the municipal level. For a few sectors (for example, the agricultural sector), the income approach is utilized at the national level and is then imputed to the regional level (for example, using acreage in various crops).

15 Labor market areas are defined in terms of commuting patterns much the same as metropolitan statistical areas are defined in the US (except that the basic building block is the municipality rather than the county). In the case of multiple inventors in different labor markets, the allocation of invention to labor market areas can be made proportionately.

---

5. Statistical models of productivity

We analyze productivity and patent activity over time and space using a model with fixed effects, that is, indicator variables for each of the municipalities or labor market areas and for each year. In this formulation, the distinctive characteristics of each municipality or labor market area are held constant, as are the distinctive characteristics of each time period. Identification is achieved through changes in productivity and patent activity within geographical areas and years.

First, we analyze the link between university inputs and productivity. In the section that follows, we consider the relationship with patents. Our models estimate the effects of university-based researchers on the productivity of local areas, and they compare the effects for the older, established (pre-1977) universities with those for the newer, smaller, and less centralized institutions established since then. The geographical areas are generally quite small, and our research design attempts to control for potential spillovers across geographical boundaries in a variety of ways. The general form of the model is:

\[
\log P_o = \alpha E_a + \beta_1 M_j + \gamma T_k + \epsilon.
\]  

(1)

The dependent variable is worker productivity, \(P_o\), output per worker, in community \(i\) in year \(t\). \(E_a\) characterizes post-secondary education in community \(i\) in year \(t\). \(M_j\) and \(T_k\) are fixed effects: \(M_j\) is a dummy variable with a value of one for municipality \(i = j\) and zero otherwise \((i \neq j)\), and \(T_k\) is a dummy variable with a value of one for year \(t = k\) and zero otherwise \((t \neq k)\). \(\alpha\), \(\beta\), and \(\gamma\) are estimated parameters, and \(\epsilon\) is an error term.

In our regressions, we measure \(E\) by the number of university-based researchers \((R)\) employed in the community. In other regressions, we distinguish between university-based researchers employed at the ‘old’ and the ‘new’ institutions \((R_o\) and \(R_n\), respectively). In still other models we distinguish those university-based researchers trained in technical specialties.

We estimate several models and variants to account for intercommunity spillovers arising from the economic activity stimulated by investment in post-secondary institutions. In the most straightforward of these extensions, we include a gravity variable summarizing the distance of each community to the universities and university researchers employed in all other communities. In these models, we include an additional variable, \(\sum w_{ij} R_i / d_{ij}\), where \(d_{ij}\) is the distance between community \(i\) and community \(j\). The gravity measure weights the university research activity in each of the other communities inversely proportional to its distance to that jurisdiction.

We also recognize that the decentralization “experiment” did not employ random assignment in the geographical distribution of new institutions of higher education. The 278 communities and 83 labor market areas without a university at the time of the adoption of the policy were not equally likely to have established a university subsequently.

Although the historical record clearly specifies that the location of only one of the new facilities was chosen for economic considerations, there may be systematic determinants of the choices of locations for these new facilities. For our purposes, the most important issue is whether the sites chosen were those which were poised for economic development and increased patent activity anyway.

To address this issue, we also present estimates of Eq. (1) using a set of instrumental variables. As instruments for the presence of a university and for the number of researchers, we employ a vector of variables indicating whether each of the following kinds of facilities was located in each community prior to the university.
expansion: military facilities; nursing schools; secondary engineering schools; and preschool teacher training facilities. Students at these facilities have a negligible effect upon current productivity, but the presence and scale of these facilities do affect the ease of expanding university presence into any community (see note 2 above). In addition, we include as instruments the number and proportion of the population of each community turning 18 years of age in each year (and thus becoming eligible for higher education). We also include as instruments the proportion of voters choosing the Social Democrats, the Liberal Party, and the Center Party in each year. The Social Democrats controlled the national government during this period, and the Minister of Education was a member of that party. The Center Party heavily represents rural interests and was strongly in support of the decentralization policy. These instruments may help explain the extent of university decentralization across geographical regions, but they are hardly direct causes of productivity variations.

Table 2 reports the coefficients of these models, ordinary least squares regressions and instrumental variables estimates. Panel A reports estimates of the log linear specification in Eq. (1). Panel B reports the results using a logarithmic specification (and incrementing the number of researchers by one, e.g., \( \ln R + 1 \)). The OLS models clearly indicate a link between the number of universities and productivity, but the presence and scale of these facilities do affect the ease of expanding university presence into any community (see note 2 above).

Note: \( Gr \) represents the coefficient for the proportion of the population of each community turning 18 years of age in each year (and thus becoming eligible for higher education). The sample consists of a panel of 3976 observations on output per worker by municipality and year.

Instruments: Five dummy variables signifying the prior presence of a military school, naval school, teacher training facility, secondary engineering school, or nursing school; three variables signifying the municipal vote shares for the Social Democrats, Liberals, and the Center Party; the municipal population 18 years of age and the fraction of the population of each community turning 18 years (and thus becoming eligible for higher education). The sample consists of a panel of 3976 observations on output per worker by municipality and year.

importance of post-graduate researchers is about eight times as large for the new institutions as for the older institutions. The pattern is unchanged when the distances among municipalities are controlled for in a gravity representation. But these latter models do suggest that there are spillovers across communities in the productivity linkages; university post-graduate researchers in one community also increase productivity in neighboring communities.

The results from the IV estimates are quite similar. These latter estimates utilize only pre-determined data on the location of infrastructure suitable for conversion to facilities for higher education, on political proclivities and demographics. The results provide no evidence that the locations chosen for university expansion were those which were otherwise poised for economic development and, presumably, for increased patent activity as well. In any case, the qualitative results are quite consistent across specifications.

Fig. 5 provide a non-statistical summary of these results. Fig. 5 plots the average productivity in those communities which received a new university and a post-graduate research staff together with those communities which did not receive a university. Productivity in each community is measured relative to its value in 1988. Fig. 5 compares the productivity of three groups of communities: those in which a new university was established; those in which a university had previously been established; those without a university. From either figure, it seems clear that output per worker in a community increased after the establishment of the university in that community. Trends in productivity in the communities with newly established universities are quite similar to those with the older established universities. Productivity trends in communities without a university are lower.

The IV results in Table 2 give this a more precise interpretation. The coefficients of model L8 suggest that the introduction of 100 additional post-graduate researchers in a newly established university augments local productivity by 4.5% while the introduction of the same number of researchers in communities containing older established universities augments productivity by 0.5%. The introduction of 100 additional researchers in a community 10 km away increases local productivity by 2.4%. These effects are precisely estimated.

The differential effects of additional university researchers at "new" and "old" institutions on productivity are consistent across models, and they do not arise simply as an artifact of the log linear specification of Eq. (1). For example, according to the simplest OLS model, L3, with a log linear specification, an augmentation of 100 post-graduate researchers at an older established university increases productivity by 0.5% while the equivalent investment at a...
newer institution increases productivity by 4.0%. Using the analogous logarithmic specification, L11, we estimate an augmentation of 100 post-graduate researchers at an older established university increases productivity by 0.4% while the equivalent investment at a newer institution increases productivity by 2.5%. These conclusions are robust to estimation by instrumental variables and also because inventors may live in one community and work in another within the same labor market area.

6. Statistical models of creativity

We analyze the effects of university decentralization on creativity in a parallel manner, using methods appropriate to the analysis of patent count variables.

We assume that the number of patents, \( \eta_{it} \), awarded in labor market area \( i \) in year \( t \) is distributed as,

\[
\text{prob}(\eta_{it} = y_{it}) = \frac{e^{-\mu_{it}} (\mu_{it})^{y_{it}}}{y_{it}!},
\]

for \( y_{it} = 0, 1, 2, \ldots \).

In this formulation, the left hand side represents the probability that the number of patents in labor market \( i \) and year \( t, \eta_{it} \), equals the number \( y_{it} \).

We further assume that

\[
\log \lambda_{it} + \log \mu_{it} = X_{it},
\]

that is, the parameter \( \lambda_{it} \) is log linear in a vector, \( X \), of regressors describing the labor market area \( i \) and the time period \( t \). If \( \mu_{it} = 1 \), the mean and the variance of the count distribution are equal, and Eq. (2) is a straightforward Poisson model. If the mean and variance of the count distribution are unequal, the parameters of the model may be represented as an equally straight forward negative binomial count model.\(^{18}\) We define a set of regressors,

\[
X_{it} = \delta E_{it} + \sum_{j=1}^{100} \beta_j L_j + \sum_{k=1994}^{2001} \gamma_k T_k,
\]

where \( E_{it} \) characterizes post-secondary educational institutions in labor market area \( i \) in year \( t \). \( L_j \) is an indicator variable with a value of one for labor market area \( j = i \) and zero otherwise\(^{19}\); \( T_k \) is an indicator variable with a value of one for year \( t = k \) and zero otherwise. As before, \( \delta, \beta, \gamma \) are parameters.

The effects of university decentralization upon innovative activity are identified by changes in measures of university activity within each labor market area over time. To estimate the model, we include a complete set of fixed effects for each time period and labor market area using a maximum likelihood estimator. As shown by Blundell et al. (2002), HHG, this is equivalent to the conditional maximum likelihood estimator proposed by Hausman et al. (1984). We test whether the estimated variance is equal to the mean (see Cameron and Trivedi, 1998, pp. 282–284) by computing the parameters of the negative binomial model.

We relate the decentralization in educational policy to the level of innovative activity, as measured by patents granted 3 years after the educational investments (see also Fischer and Varga, 2003 and Verspagen and De Loo, 1999). In particular, for each labor market area and year, we record the number of university-employed post-graduate researchers \( R_n \). We also record the number of research staff at each university employed in technical research specialties.

Table 3 presents the basic results. The table relates the number of patents in any labor market area and year to the number of post-graduate researchers employed at universities in that labor market. Research staffs are further disaggregated between those employed at new (\( R^n \)) and old (\( R^o \)) universities for all staff and for those in technical occupations.

Columns 1, 2, and 3 suggest that the number of post-graduate researchers is associated with higher levels of innovative activity, holding constant the important unmeasured characteristics of these differing labor market areas. The total number of patents in these regions is 15,805 during the 1994–2001 period or about 200 per year in a given labor market area. From column 1, the addition of a single post-graduate researcher increases the number of patents in any labor market area by a factor of \( \exp(0.000113) \) or by almost 0.01% in any year.

In column 2 (model M2), we disaggregate the research staff by those employed at the old universities and those employed at the new institutions. Both measures are highly significant, but the coefficient estimated for researchers at the new universities (0.00244) is larger by an order of magnitude than the coefficient estimated for researchers at the old established universities. When researchers in scientific and technical occupations are considered separately, the significance of the coefficient measuring post-graduate staff is reduced (to the 5–10% level for a one-tailed test) at new universities. However, the magnitude of the coefficient for researchers at new universities is again larger by an order of magnitude than is the estimated coefficient for researchers employed at the older institutions.
Table 3 also presents the results when the Poisson models are estimated by the technique of instrumental variables (see Nichols, 2007, for a discussion of Poisson count models estimated by IV methods). In these models, N1 through N3, we use the same variables as instruments that are used in the models of productivity reported in Table 3. The results are robust to this more general method of estimation. The magnitudes of the coefficients are larger, suggesting stronger effects upon productivity, but the \( t \) ratios of the coefficients are somewhat smaller.

In Appendix Table A1, we generalize the estimation still further, using the negative binomial model. We relax the maintained hypothesis of the Poisson model that the mean and the variance of the count distribution are equal, but we follow HHG in estimating separately a common mean and a common variable for the method of estimation. The magnitudes of the coefficients are somewhat smaller.

Conditional upon the establishment of an educational institution in a region, the marginal effect of an increase in the research staff upon patent activity is not trivial. And the marginal effects on creativity of adding research staff at the new institutions is estimated to be consistently larger than the effects of adding staff at the old, more established institutions.

For example, from model M2 it is estimated that an additional research complement of 10 individuals at a new institution leads to an increase in patents of about 2.4% while a similar increase in research staff at an old institution leads to an increase in patents of about 0.1%. This difference does not appear to arise from a different mix of technical and non-technical research staffs at the two institutions. For example, from model M3 which considers only post-graduate researchers in technical specialties, an increase of 10 technicians yields an increase in patents of 3.8% in the newer institutions and about 0.2% in the older institutions. Of course all these comparisons abstract from the many other, and presumably more important, aspects of these different labor market regions which affect creativity and innovation. The fixed effects distinguishing these one hundred labor market areas are large and highly significant in all specifications.

7. Spillovers, externalities, and interactions

How localized are the productivity and creativity increases attributable to these public investments? The spatially disaggregated data on individual municipalities and labor market areas provides some opportunity to explore the extent of spatial agglomeration and externalities.

Table 2 hints at the importance of spillovers in productivity gains over space. In all of the statistical models reported, the gravity measure is statistically significant, suggesting the presence of spatial agglomeration. However, the values of Moran’s I Statistics are also quite large, suggesting that the simple gravity model does not capture the underlying spatial relationship very well.

</table>

As an alternative, we consider the general spatial lag model, incorporating spatial structure explicitly into the model:

\[
\log P_{it} = \rho \sum_{j=1}^{n} W_{ij} \log P_{jt} + E_{it} + \beta_{j} M_{jt} + \gamma_{k} T_{kt} + \varepsilon_{it}. \tag{5}
\]

In this formulation, the productivity of labor in any municipality also depends upon the productivity of labor in neighboring towns. In response to an exogenous change in university investment in one municipality, productivity in neighboring municipalities may be enhanced as well. In the spatial error formulation, \( \rho \) indicates that productivity depends directly upon the productivity of other municipalities, where \( W_{ij} \) are the weights. Analogously, the parameter \( \lambda \) is the coefficient in the spatial autoregressive structure, and \( W_{ij} \) are the weights for the errors in other municipalities. If there are no a priori reasons to suppose that the spatial interaction patterns are different, then \( W_{ij} = W_{ji} \), and \( \rho \) and \( \lambda \) are not separately identified.

In this spatial application, we assume \( W_{ij} = W_{ji} = 1/d_{ij}^{2} \), that is, we assume that the weight matrix is of the form of the gravity model. (See Anselin, 1988, pp. 16–28.) If \( \rho \) defines the autoregressive spatial structure in Eq. (5), \( \lambda = 0 \), we can estimate the Spatial Autoregressive Model (SAR):

\[
\log P_{it} = \rho \sum_{j=1}^{n} \left(1/d_{ij}^{2}\right) \log P_{jt} + E_{it} + \beta_{j} M_{jt} + \gamma_{k} T_{kt} + \varepsilon_{it}. \tag{6}
\]

Alternatively, if \( \lambda \) defines the autoregressive spatial structure, \( \rho = 0 \), we can estimate the Spatial Error Model (SEM):

\[
\log P_{it} = E_{it} + \cdots + \varepsilon_{it}. \tag{7}
\]

Table 4 reports the coefficients of the SAR and SEM models, estimated by maximum likelihood methods, assuming normality of the error terms. As reported in the table, when spatial autocorrelation is recognized in the models, the coefficients of the other variables are reduced in magnitude and statistical significance. But the basic pattern of coefficients is unchanged. The alternate models of spatial autocorrelation yield quite similar results in terms of magnitude and significance. Either measure of spatial dependence, \( \rho \) or \( \lambda \), is highly significant.

In models relating productivity to the number post-graduate researchers, the coefficient on the number of researchers in the same community is significant. The magnitudes of the coefficients on university researchers are smaller in these models which incor-

---

20. Note that we have been unable to estimate the negative binomial model using instrumental variables.

21. Specifically, at the point of means, from equation M3 10 additional post-graduate researchers yield 2.05 patents in the new institutions and 0.16 patents in the old institutions.

22. Note again that we cannot distinguish, in these models, between the direct effects of university resources in stimulating innovation and the indirect effects arising from the location of other facilities in response to the investments in university facilities.

23. For example, for model L1 Table 3, the value of Moran’s I is 8.741. When the model is extended to include the gravity representation of space, in L2, the value of Moran’s I is smaller, 7.823. However this latter value is still highly significant statistically, suggesting the presence of spatial autocorrelation in the data.

24. Anselin et al. (1997) is the standard reference documenting these spatial models.
porate spatial autocorrelation and the broader productivity linkages among municipalities. In all cases, the coefficients indicate that productivity is higher in communities in which more university-based researchers are employed. These results are significant at the 0.15 level. We also find clear evidence that this effect is substantially larger for those researchers employed at the newer institutions than for those employed at the older institutions. Finally, we find that productivity is greater in communities in closer proximity to pools of university-based researchers. This latter finding is consistent with results reported by Adams (2002) for US academic institutions.

Spillovers in creativity are less likely to be uncovered, in part due to the more aggregate representation of space. As noted above, because inventors may live in one municipality and work in another, we can only measure patent counts annually at the level of the labor market area. There are only 100 labor market areas in Sweden (as compared to 284 municipalities), and their boundaries are chosen to maximize the within-area economic relationships relative to the between-area relationships. Nevertheless, it is possible to conduct a parallel effort to test for spatial linkages.

Consider the spatial Poisson model, Eqs. (2)–(4) but in which Eq. (4) is replaced by

\[ X_{it} = \xi \sum_{j=1}^{100} W_{ij} \eta_j + \delta E_{it} + \sum_{j=1}^{100} \beta_j L_j + \sum_{k=1994}^{2001} \gamma_k T_k. \]  

In this model, the patent count in any one labor market is related to the patent count in all other labor market areas. As before, \( W_{ij} \) is a weight matrix involving the distances between labor market areas, and \( \xi \) is a parameter. A variant of this model, the class of spatial Poisson regression models, is described in Best et al. (2000).25 Related models, with epidemiological applications, are discussed in Elliott et al. (2001). The model can be estimated iteratively using Bayesian methods.

Table 5 reports the results of this investigation of potential spillovers in patent activity. We use the nearest neighbor technique26 to define the weight matrix, \( W_{ij} \), again using \( 1/d_{ij}^2 \) as elements of \( W_{ij} \). We investigate the same models analyzed in Table 4. Parameters of the spatial Poisson model are estimated using Geogugs.27 The magnitudes of the estimated coefficients are larger in these estimates, but the pattern of the coefficients is identical to those reported previously. The coefficient of the variable measuring the number of university-affiliated post-graduate researchers is significant, as is the number at new institutions, and the number of technical researchers at new institutions. The coefficient on the number of researchers is consistently higher for the new universities than for the old institutions.

There is no evidence in these results of spatial autocorrelation in the patent counts across labor market areas. The coefficient \( \xi \) is not precisely estimated to be zero, that is, its standard error is quite large in all specifications. This contrasts with our finding of spatially correlated productivity effects. Of course, the productivity effects are measured for much smaller geographical units of observation. The regions used for the analysis of patents are both larger.28

Note: \( \xi \) represents the coefficient for \( \sum_{j=1}^{100} W_{ij} \eta_j \), where \( \eta_j \) is the patent count in labor market \( j \) in year \( t \) and the weight matrix, \( W_{ij} \), is based upon the nearest neighbor method. All models include fixed effects for 100 labor market areas and eight time periods. The sample consists of a panel of 800 observations on patent counts by labor market area and year.

8. The attenuation of spillovers

The models of productivity reported in Tables 2 and 4 support a more detailed investigation of the spatial pattern of productivity spillovers. These results suggest that there are substantial, but highly localized, spillovers in productivity gains over space. Table 7 summarizes the implications of our estimates based on log linear and logarithmic specifications, OLS and IV estimation, as well as SAR and SEM specifications of spatial errors. The estimates clearly imply that these productivity gains are highly localized. The spillovers from researchers employed at the old established institutions are concentrated; roughly 40% of the cumulative gain in productivity is within 10 km of the institution. For new universities, where the estimated effect on productivity is larger, the attenuation is even more pronounced. Between one-third and one-half of the total effect upon productivity is registered within 5 km of the university. The numerical estimates vary with the details of the statistical models, but the patterns are the same; a rapid

---

25 In the application by Best et al. (2000), a slightly different specification of the spatial relationship in (4) is used to analyze spatial correlation in the distribution of counts measuring the incidence of respiratory ailments across geographical areas. In an analogous application, Ickstadt and Wolpert (1997) analyzed the spatial distribution of hickory trees in different plots situated in a forest.

26 See Anselin (1988) for a thorough discussion.

27 We are grateful to Nicky Best for making an advance version of release 4.1 available to us for this purpose. In our applications, we use 1000 “burn in” iterations to derive starting values for the coefficients, and we use another 1000 iterations to produce coefficient estimates. Results are insensitive to these choices. These results are also insensitive to the inclusion or exclusion of fixed effects.

28 For example, the Stockholm labor market area includes some 27 municipalities.
fall-off with distance, more rapidly for investments made at the newly established institutions. These findings are consistent with a growing body of empirical research in other countries on the agglomerative tendencies of so-called “knowledge industries.” Saxenian (1994), for example, suggested that knowledge generated at a firm in the US is more likely to spill out locally if it originates in a small firm. Conversely, Henderson’s analysis (2003) of US high tech industry at the plant level suggests that smaller firms are more likely to benefit from local agglomeration. Rosenthal and Strange (2003) found that small establishments in the knowledge industry have larger effects on locational attractiveness than larger ones. In an earlier paper using micro data from Dunn and Bradstreet, they also found (Rosenthal and Strange, 2001) that proxies for knowledge spillovers in the US affect firm agglomeration only at the very local (postal code) level. Two other analyses of US industry suggest that local externalities and agglomerative economies greatly attenuate with distance. Rosenthal and Strange (2005) analyzed manufacturing, trade and services in New York, finding that agglomerative effects on firm births and employment decline rapidly over space. They attribute this attenuation to the “high costs of moving ideas” over space. They also analyzed nationally representative data for the US (Rosenthal and Strange, 2008), finding that the effect of urbanization economies on worker productivity may be only about half as large at distances over 8 km as it is at closer distances. (See also Agrawal et al. (2008).)

The results of our analysis of Swedish productivity are consistent with these findings. We find highly significant, but highly localized, external effects arising from the geographical locations chosen for these new institutions of higher education. Finally, it is also possible, at least in principle, to estimate the net change in output and patent activity arising from the spatial rearrangement of researchers. Using the results presented in Table 3, for example, the level of innovation in each region can be computed under the counterfactual of no decentralization of Swedish universities. To do this, we reallocate the researchers, employed in the 25 newly established institutions during the period 1995–2001, back to the 11 institutions which had been in existence in 1987. We reallocate researchers to the pre-existing institutions in proportion to their distribution in 1987. We reallocate researchers to the pre-existing institutions in proportion to their distribution in 1987. Data on the number of workers in each municipality allow us to compare the value of total output with output under the counterfactual. A comparison of this counterfactual with realized output yields the net change in GDP arising from the policy of decentralizing higher education. Using the same six statistical models reported in Table 7, we estimate the net effect of this spatial rearrangement to be an increase in GDP of between 0.01% and 0.10%. These calculations suggest that the increment to GDP is, in fact, quite large. Indeed, it is roughly as large as the initial contribution to GDP of these workers.

9. Conclusion

During the past 15 years, Swedish higher education policy encouraged the decentralization of post-secondary education. We investigate the spatial and economic effects of this decentralization on productivity and creativity. We provide several tests of the hypothesis that the establishment or expansion of university research in a region improves productivity and enhances creativity. We find systematic evidence that output per worker is higher and the award of patents is greater in regions that have received larger university-based investments as measured by the number of researchers employed on staff. We also find that changes in productivity are higher and new patent awards are more frequent in regions in which the “new” universities and institutions are located than in regions in which the “old” universities are located.

Our analysis permits us to hold constant the important factors affecting economic activity by municipality, labor market area and time, thereby improving the precision of estimates. The results are broadly consistent across theoretical models and statistical

Using the coefficients in model N3 in Table 3, we estimate that the net effect of this spatial rearrangement on patents to be about zero. We can also use the results presented in Tables 2 and 4 to estimate the level of productivity under the counterfactual of no decentralization of Swedish universities. (We use the same counterfactual, and again, we reallocate researchers to the pre-existing institutions in proportion to their distribution in 1987.) Data on the number of workers in each municipality allow us to compare the value of total output with output under the counterfactual. A comparison of this counterfactual with realized output yields the net change in GDP arising from the policy of decentralizing higher education. Using the same six statistical models reported in Table 7, we estimate the net effect of this spatial rearrangement to be an increase in GDP of between 0.01% and 0.10%. These calculations suggest that the increment to GDP is, in fact, quite large. Indeed, it is roughly as large as the initial contribution to GDP of these workers.

Note: All models include fixed effects for 100 labor market areas and 284 municipalities. Productivity models are estimated for 1985–1998. Creativity models are estimated for 1994–2001.

These models use the number of post-doctoral university researchers in technical specialties and are estimated for 1993–1998.

29 Specifically the estimated increase in GDP arising from the university decentralization, as computed from each of these six models is: 0.01% (L4); 0.01% (L8); 0.04% (L12); 0.05% (L16); 0.11% (S2); 0.07% (S4).
results. There is strong evidence that an expansion of university presence in a community, measured by the number of university-based researchers, is associated with increased output per worker in that community and with increases in the patents awarded to inventors in that labor market area.

The importance of the university in affecting productivity and creativity is consistently larger at the margin for the new institutions. For patents, at least, this could arise if the new institutions specialize more narrowly in technical specialties than do the more traditional institutions of higher education. Of course, some of the new institutions are, in fact, expansions of institutions that formerly provided some technical training (e.g., military facilities). This may explain some of the differences.30

The productivity gains are highly localized. The spillovers from researchers employed at the old established institutions are concentrated. Roughly 40% of the cumulative gain in productivity is within 10 km of the institution. For the new universities the attenuation is even more pronounced; between one-third and one-half of the total effect upon productivity is registered within 5 km of the university.

Our findings are consistent with a substantial, but highly attenuated, external effect of investment in higher education, augmenting the productivity of local areas and the local economies in which they are situated.

P4 uses the number of post-doctoral university researchers in technical specialties and is estimated for 1993–1998.

30 Without conducting a more anthropological investigation, it is not possible to resolve this. But some collateral information is suggestive of a more commercial and industrial orientation among (some) of the new institutions. Thus, Karlstad University (http://www.kau.se/research/forests.lasso) in the heart of the Swedish pulp and paper region boasts a substantial research program in “Forests, environment, and materials,” and Luleå University (http://www.ltu.se/inst) has an institute of “Applied Physics . . .” and another of “Applied Chemistry . . .”
